Index

1. Technical-Subject Index

A Self-Balancing Capacitance Bridge. Foley..797–801
Acceleration With a Vacuum Tube, The Measurement of. Ramberg.....735–40
Accuracy of Temperature Measurements on Coil Surfaces. Beede, Cain.....586–90; disc. 590
Adjustable Frequency Control of High-Speed Induction Motors. Heumann.....719–25
Adjustable-Speed A-C Brush-Shifting Motor, Impedance Relationships of the. Baumann.....1460–2
Advancements in the Design of Long-Scale Indicating Instruments. Rowell, Millar.....155–60
Aging Tests on Class A Insulation, Preliminary Report on Laboratory. (Committee Report).....879–81; disc. 881
Aids for Electromechanical System Development, Laboratory. Newton, White....315–19; disc. 319
AIEE Officers and Committees for 1947–48....1724–37
AIEE Publication Policy Becomes Effective in January 1947, New.....1721–3
Air Circuit Breakers, Selective Tripping of Low-Voltage. Deans.....971–6; disc. 976
Air, Determination of Corona Starting Voltages for Nonuniform Fields in. Hutton..1674–9; disc. 1680
Air Gap Reactance of Polyphase Machines, The. Alger, West.....1331–43
Air Switches for Line Sectionalizing and Load Transfer, Automatic Control of. Rich, Kirwen.....293–9; disc. 299
(Air Transportation) Electric Equipment Required in a Modern 6-Component Wind Tunnel Model Suspension System. Cox.....1258–66
(Air Transportation) The Calibration of Ignition Crest Voltmeters. Davis, Warren....99–104; disc. 104
Airborne Magnetometers for Search and Survey. Felch, Means, Slonczewski, Parratt, Rumbaugh, Tickner.....640–50
Airborne Radar to Increase Airline Safety, Using. Ayer.....1387–95
Aircraft, A Capacitance-Type Fuel-Measurement System for. Pearson.....1363–8
Aircraft Alternators Using Electronic Frequency Changers, Parallel Operation of. Bowlus, Nims.....31–8
Aircraft D-C Generators, An Integrated Control System for. McClinton.....94–8
Aircraft, Electric Drive for. Crom.....1359–62
Aircraft Electric Power Protective Systems. Austin.....1375–82
Aircraft Generator Power Center, D-C. Bottemiller.....1267–70
Aircraft, Ground Power Supply for Modern. Owen, Murray, Rosenstein.....1296–1303
Aircraft Window Deicing, Control and Power Systems for. Mershon.....1400–05
Airline Safety, Using Airborne Radar to Increase. Ayer.....1387–95
Airplanes, Automatic Temperature Control for Transport. Hedges.....1197
Airport Runway and Approach Lighting. Kevern.....1396–9
Alloy, Hiperco—A Magnetic. Stanley, Yensen..714–8
A-C Brush-Shifting Motor, Impedance Relationships of the Adjustable-Speed. Baumann.....1460–2
A-C Crane Motors, A Thrustor Lowering Control System for. Schwarz-Kast.....139–44; disc. 144
A-C Power Transmission, Economics of Long-Distance. Crary, Johnson.....1092–9; disc. 1099
A-C Stator Windings, The Application of Surge Comparison Testing Equipment to Fractional Horsepower. Buchanan.....1356–8
A-C Turbine Generators, Liquid Cooling of. Fechheimer.....553–61; disc. 561
Alternators Using Electronic Frequency Changers, Parallel Operation of Aircraft. Bowlus, Nims..31–8
Altitude Flashover and Corona Correction on Small Ceramic Bushings. Pendleton.....1324–30
Aluminum Anodes, Cathodic Protection of Steel Water Tanks Using. Sudrabin, Mears.....197–200
Ampere-Demand Meter, A Polyphase Thermal. Petzinger.....167–74
Amplifier, Direct Coupled Oscillograph. Christian.....1383–6
Amplifier, Some Fundamentals of a Theory of the Transductor or Magnetic. Lamm.....1078–85
Amplifier Using Biased Saturable Core Reactors, A Balanced. Kirschbaum, Harder.....273–8
Analogy, Dimensionless Analysis of Servomechanisms by Electrical. Part I. McCann, Herwald..111–18
Analogy, Solution of the General Voltage Regulator Problem by Electrical. Harder..815–25; disc. 825
Analysis, An Extension of Impact Speed-Drop. Crever.....191–6
Analysis and an Optimum Synthesis of Linear Servomechanisms, The. Herr, Gerst.....959–70
Analysis and Equivalent Circuit of a Variable-Ratio Frequency Changer, Tensorial. Kron...1503–06
Analysis of Motor Selection for Brass-Slab Rolling-Mill Service, An. Berkeley.....185–9; disc. 189
Analysis of Servomechanisms by Electrical Analogy, Dimensionless. Part I. McCann, Herwald..11–18
Analysis of Speed Regulators Under Impact Loads, General. McCann, Osbon, Kirschbaum..1243–52
Analysis to Automatic Control Systems, The Application of Lead Networks and Sinusoidal. Schwartz.....69–76; disc. 76
Anodes, Cathodic Protection of Steel Water Tanks Using Aluminum. Sudrabin, Mears.....197–200
Anodizing Applications, Automatically Controlled Copper-Oxide Rectifiers for Electroplating and. Buckley.....181–4
Apparatus, Gaseous Insulation for High-Voltage. Camilli, Chapman.....1463–9; disc. 1469
Application of Complex Logarithmic and Geometric Mean Distances, Theory and. Higgins.....12–16
Application of Heterodyne Modulation to Wide-Banded Frequency-Modulated Television Relays, The. Boothroyd.....1126–30
Application of Lead Networks and Sinusoidal Analysis to Automatic Control Systems, The. Schwartz.....69–76; disc. 76
Application of Rural Carrier Telephone System. Bartlink, Cook, Cowan, Messmer....511–18; disc. 517
Application of Storage Batteries to the Control of Switchgear, The. Hoxie.....1561–9; disc. 1569
Application of Supersonic Flaw Detectors, Design and. Erdman.....1271–6
Application of Surge Comparison Testing Equipment to Fractional Horsepower A-C Stator Windings, The. Buchanan.....1356–8
Application of Synchronous and Induction Motors to Chippers, The. Baker, Lory.....1070–7
Application of Western Union Multiplex to Navy Radio, The. Hoover.....1478–82
Applications, Automatically Controlled Copper-Oxide Rectifiers for Electroplating and Anodizing. Buckley.....181–4
Applications, Frequency Shift Telegraphy—Radio and Wire. Davey, Matte.....479–93; disc. 493
Applications of the Electrodynamic Instrument Mechanism. Corson, Millar.....1131–6
Approach Lighting, Airport Runway and. Kevern.....1396–9
Approach to Speed and Tie Line Control, Theoretical. Brandt.....24–9; disc. 29
Arc-Back Testing of Graphite. Pakala, Cuculiu..439–42
Arrester Discharges, Field Research on Lightning. McCann, Beck.....625–9; disc. 629
Arresters—Tidd 500-Kv Test Lines, Transformers and Lightning. Lane, Hodnette, Bellaschi, Beck.....1613–18; disc. 1618
Asymmetrical Stator and Rotor, Equivalent Circuit of the Primitive Rotating Machine With. Kron.....17–23; disc. 23
Automatic Circuit Recloser, An Improved. Wallace.....255–8; disc. 259
Automatic Control of Air Switches for Line Sectionalizing and Load Transfer. Rich, Kirwen.....293–9; disc. 299
Automatic Control of Hydroelectric Generating Stations. Brown, Derr.....343–55; disc. 355
Automatic Control Systems, The Application of Lead Networks and Sinusoidal Analysis to. Schwartz.....69–76; disc. 76
Automatic Operation of Electric Boilers. Eaton.....1061–8; disc. 1068
Automatic Switching Schemes for Capacitors. Cuttino.....311–14
Automatic Switching, The Economics of Using Capacitors in Amounts to Require. Butler.....322–7; disc. 327
Automatic Temperature Control for Transport Airplanes. Hedges.....1197
Automatically Controlled Copper-Oxide Rectifiers for Electroplating and Anodizing Applications. Buckley.....181–4
Auxiliary-Power Equipment, Modern Railway Passenger-Car. MacLeod, Hause.....930–8

B

Balanced Amplifier Using Biased Saturable Core Reactors, A. Kirschbaum, Harder.....273–8
Balancing Capacitance Bridge, A Self-. Foley..797–801
Band-Width Characteristics of Pulse Modulation, Distortion and. Kraus, Ordung.....984–8
Basic for Distance Relaying on 3-Phase Systems, Fundamental. Lewis, Tippett.....694–708; disc. 708
(Basic Sciences) Determination of Corona Starting Voltages for Nonuniform Fields in Air. Hutton.....1674–9; disc. 1680
(Basic Sciences) Diffusion of Electric Current into Rods, Tubes, and Flat Surfaces. Miller.....1496–1502
(Basic Sciences) Eddy Currents in Disks: Driving and Damping Forces and Torques. Moore.....1–10; disc. 10
(Basic Sciences) Effective Resistance of Isolated Nonmagnetic Rectangular Conductors. Dwight.....549–52
(Basic Sciences) Machine Computation of Power Network Performance. Dunstan....610–20; disc. 621
(Basic Sciences) The Physics of Electronic Semiconductors. Pearson.....209–14
(Basic Sciences) The Probable Breakdown Voltage of Paper Dielectric Capacitors. Brooks.....1137–44; disc. 1144
(Basic Sciences) Theory and Application of Complex Logarithmic and Geometric Mean Distances. Higgins.....12–16
Basic Servomechanism Types, A Comparison of Two. Harris.....83–92; disc. 92
Basis for Generator Reserve, Outage Expectancy as a. Seelye.....1483–8
Batteries to the Control of Switchgear, The Application of Storage. Hoxie.....1561–9; disc. 1569
Bearing Deviation Indicator for Sonar. Schuck, Stedman, Hathaway, Butz.....1285–95
Bearing Practice for Vertical Water Wheel Generators, Modern. Laffoon, Baudry.....363–9; disc. 369
Bearings at the Bonneville Plant of the Corps of Engineers, War Department, The Design and Performance of the Vertical Generator Thrust. Lewis, Gordon.....1231–7; disc. 1237
Board of Directors, Report of the.....1698–1720
Boilers, Automatic Operation of Electric. Eaton.....1061–8; disc. 1068
Bonneville Plant of the Corps of Engineers, War Department, The Design and Performance of the Vertical Generator Thrust Bearings at the. Lewis, Gordon.....1231–7; disc. 1237
Brakes and Drum Brakes for PCC Cars, Recent Developments in Track. Vouch.....302–04
Braking by Self-Excitation of Squirrel-Cage Motor, Dynamic. Srinivasan, Thomas.....145–8
Braking of a Single D-C Series Motor, Dynamic. Leitch.....149–54
Braking of Two D-C Series Motors, Dynamic. Leitch.....787–91
Braking Resistors and Control for Diesel-Electric Locomotives. Weiser.....229–32
Braking, The Design of New York Subway Motors for Dynamic. Widell.....808–10
Brass-Slab Rolling-Mill Service, An Analysis of Motor Selection for. Berkley.....185–9; disc. 189
Breakdown Voltage of Paper Dielectric Capacitors, The Probable. Brooks.....1137–44; disc. 1144
Breaker Current Measurements During Reignitions and Recovery, Circuit-. Lewis....1253–7; disc. 1257
Breakers, An Improved Overcurrent Tripping Device for Low-Voltage Circuit. Rawlins, Sandin.....1149–53; disc. 1153
Breakers, Selective Tripping of Low-Voltage Air Circuit. Deans.....971–6; disc. 976
Bridge, A Self-Balancing Capacitance. Foley..797–801
Bridges, Electronic Null Detectors for Use With Impedance. Lamson.....535–40
Broadcast Stations, Television Equipment for. Lawrence.....443–52
Broken Conductor Effect on Sags in Suspension Spans. Bisiri, Landau.....1181–8
Brush Characteristics by the Dynamotor Method, Dynamic. Herman.....759–63

Brush-Shifting Commutator Motor (Schrage Type), The Circle Diagram of the Polyphase. Franklin.....1667–72; disc. 1672
Brush-Shifting Motor, Impedance Relationships of the Adjustable-Speed A-C. Baumann.....1460–2
Burning of Wood Structures by Leakage Currents. Rus.....279–84; disc. 285
But Where No Overhead Facilities Exist, Can the Trolley Coach Compete Economically With the Gas or Diesel. Gaus.....264–8; disc. 268
Bushings, High Altitude Flashover and Corona Correction on Small Ceramic. Pendleton.....1324–30

C

Cable Carrier System, An Improved. Black, Brooks, Wier, Wilson.....741–46; disc. 746
Cable Carrier, Systems, New Test Equipment and Testing Methods for. Tidd, Rosen, Wenk..726–30
Cable Network, Frequency Division Techniques for a Coaxial. Crane, Dixon, Huber.....1451–5
Cable Switching, Resistors for 138-Kv. Sadler, Blakeslee.....39–46; disc. 46
Cable Telegraphy, Some Modern Techniques in Ocean. Cramer.....494–500; disc. 500
Cables, Gas Pressure for Telephone. Giese.....471–8
Cables, Internal Corona Discharges in Insulated. Greenfield.....591–600; disc. 600
Cage Motor, Dynamic Braking by Self-Excitation of Squirrel-. Srinivasan, Thomas.....145–8
Cage Rotor, The "Cooperspun" Squirrel. Anderson.....1312–14
Calculating Probability of Generating Capacity Outages. Lyman.....1471–7; disc. 1477
Calculating Stability, The Transient-Energy Method of Magnuson.....747–55; disc. 755
Calculation of Leakage Reactance of Induction Motors, Some Phases of. Liwschitz, Formhals.....1409–12; disc. 1412
Calculation of Slot Constants. Puchstein.....1315–22; disc. 1322
Calculations for Single-Phase Magneto, Shading Coil. Evans.....134–7; disc. 137
Calculations, Ignitor Characteristic and Circuit. Marshall.....1519–24
Calculations on Shaded Pole Motors, Performance. Trickey.....1431–8; disc. 1438
Calibration of Ignition Crest Voltmeters, The. Davis, Warren.....99–104; disc. 104
Canada, Electric Furnace Practice in. Balleny..917–24
Capacitance Bridge, A Self-Balancing. Foley..797–801
Capacitance Fuel Gauges. Clark, Adolphe.....1189–96; disc. 1196
Capacitance-Type Fuel-Measurement System for Aircraft, A. Pearson.....1363–8
Capacitor Motor, The Equivalent Circuit of the. Chang.....631–40
Capacitor Motors, A Design Method for. Lloyd, Chang.....651–7; disc. 657
Capacitor Start Motors, A Design Method for. Chang.....1369–74
Capacitors, Automatic Switching Schemes for. Cuttino.....311–14
Capacitors in Amounts to Require Automatic Switching, The Economics of Using. Butler..322–7; disc. 327
Capacitors, The Probable Breakdown Voltage of Paper Dielectric. Brooks.....1137–44; disc. 1144
Capacity Determined by the Probability Method, Generating Reserve. Calabrese.....1439–50
Capacity Outages, Calculating Probability of Generating. Lyman.....1471–7; disc. 1477
Capacity Problems of a Combined Hydro and Steam System, Probability Methods Applied to Generating. Loane, Watchorn.....1645–54; disc. 1654
Car Equipment for New York City's Subway System, Modern. Cordts.....247–9; disc. 250
Car, Some Recent Developments in the PCC. Cooper.....288–92; disc. 292
Carrier Channels, Operation of Power Line. Lenner.....888–93; disc. 893
Carrier System, An Improved Cable. Black, Brooks, Wier, Wilson.....741–6; disc. 746
Carrier System for Power Lines, A New Single-Side-Band. Lenehan.....826–30; disc. 830
Carrier Systems, New Test Equipment and Testing Methods for Cable. Tidd, Rosen, Wenk...726–30
Carrier Telephone System, Application of Rural. Bartelink, Cook, Cowan, Mesmer..511–17; disc. 517
Carrier Telephone System for Rural Service, A. Barstow.....501–07
Cars, Motor Control for Latest New York Transit System Subway. Riley.....900–03
Cars, Recent Developments in Track Brakes and Drum Brakes for PCC. Vouch.....302–04
Cathode-Ray Oscilloscope, Quantitative Determination of Magnetic Properties by Use of. Zamsky..783–7
Cathode-Ray Sensing Element, A Magnetic Compass With. Kliever, Syrdal.....529–34
Cathode-Ray Spectrograph, The. Feldt, Berkley.....105–10
Cathodic Protection of Steel Water Tanks Using Aluminum Anodes. Sudrabin, Mears.....197–200
Cavities at 10,000 Megacycles, Measurement of High Q. Lange.....161–6
Cell, Electrical Characteristics of the Junction in a Simplified Selenium Rectifier. Angello...175–80
Cellulose Insulation Impregnated With Semi-conducting Liquids, The Dielectric Properties of. Clark.....55–62; disc. 62
Center, D-C Aircraft Generator Power. Bottemiller.....1267–70
Ceramic Bushings, High Altitude Flashover and Corona Correction on Small. Pendleton.....1324–30
Changer, Suddenly Applied Loads on a Variable-Ratio Frequency. Carter, Maginniss, Rothe....1489–95
Changer, Tensorial Analysis and Equivalent Circuit of a Variable-Ratio Frequency. Kron.....1503–06
Changers, Parallel Operation of Aircraft Alternators Using Electronic Frequency. Bowlus, Nims..31–8
Channels, Operation of Power Line Carrier. Lenner.....888–93; disc. 893
Characteristic and Circuit Calculations, Ignitor. Marshall.....1519–24
Characteristics by the Dynamotor Method, Dynamic Brush. Herman.....759–63
Characteristics of Current Transformers During Faults, Part II. Rothe, Concordia.....731–4
Characteristics of Pulse Modulation, Distortion and Band-Width. Krauss, Ordung.....984–8
Characteristics of Resistance Welding Tools, Electrical. Callender.....393–404
Characteristics of the Junction in a Simplified Selenium Rectifier Cell, Electrical. Angello.....175–80
Charging Current at High Voltage, The Interruption of. Leeds, Van Sickle.....373–80; disc. 381
Cheyenne Wells, Colo., Rural Radiotelephone Experiment at. Moore, Seyler, Wright.....525–8
Chippers, The Application of Synchronous and Induction Motors to. Baker, Lory.....1070–7
Chopped Waves on Transformers, A Study of the Relative Severity of Steep Front Waves and. Vogel.....64–6; disc. 66
Circle Diagram of the Polyphase Brush-Shifting Commutator Motor (Schrage Type), The. Franklin.....1667–72; disc. 1672
Circuit-Breaker Current Measurements During Reignitions and Recovery. Lewis..1255–7; disc. 1257
Circuit Breakers, An Improved Overcurrent Tripping Device for Low-Voltage. Rawlins, Sandin.....1149–53; disc. 1153
Circuit Breakers, Selective Tripping of Low-Voltage Air. Deans.....971–6; disc. 976
Circuit Calculations, Ignitor Characteristic and. Marshall.....1519–24
Circuit Feed Regulator, A New Grinding. Jones.....1240–2
Circuit of a Variable-Ratio Frequency Changer, Tensorial Analysis and Equivalent. Kron....1503–06
Circuit of the Capacitor Motor, The Equivalent. Chang.....631–40
Circuit of the Induction Motor, Leakage Reactance of the Squirrel Cage Rotor With Respect to the Stator Harmonics and the Equivalent. Liwschitz.....1407–08
Circuit of the Primitive Rotating Machine With Asymmetrical Stator and Rotor, Equivalent. Kron....17–23; disc. 23
Circuit Recloser, An Improved Automatic. Wallace.....255–8; disc. 259
Circuits, Grounding of Instrument Transformer Secondary. (Committee Report).....419–20
Circuits, Sectionalizing and Internal Transformer Fusing on Rural Power. Watkins..383–8; disc. 388
City Transportation, Trolley Coaches and PCC Street Cars Provide Successful. Clardy.....925–9
Class A Insulation, Preliminary Report on Laboratory Aging Tests on. (Committee Report).....879–81; disc. 881
Coaxial Cable Network, Frequency Division Techniques for a. Crane, Dixon, Huber.....1451–9
Code Modulation, Pulse. Black, Edson.....895–9
Coil Calculations for Single-Phase Magnets, Shading. Evans.....134–7; disc. 137
Coil Surfaces, Accuracy of Temperature Measurements on. Beede, Cain.....586–90; disc. 590
Coils, Data on the High-Frequency Resistance of Coils. Wittig.....764–9
Collectors for High-Speed Service, Developments in Current. Langer.....51–4
Colorado, Rural Radiotelephone Experiment at Cheyenne Wells. Moore, Seyler, Wright.....525–8
(Committee Report) Grounding of Instrument Transformer Secondary Circuits.....419–20
(Committee Report) Preliminary Report on Laboratory Aging Tests on Class A Insulation..879–81; disc. 881
(Committee Report) Present-Day Grounding Practices on Power Systems. (Committee Report).....1525–48; disc. 1548
(Committee Report) Progress in Power Generation—1940–46.....1681–97
(Committee Report) Relay Protection of Power Transformers.....911–15; disc. 915
Committees for 1947–48, AIEE Officers and....1724–37
(Communication) A Carrier Telephone System for Rural Service. Barstow.....501–07
(Communication) A Frequency Modulation Telegraph Terminal Without Relays. Cusack, Michon.....1165–70; disc. 1170
(Communication) A New Microwave Television System. Wentz, Smith.....465–70
(Communication) A 60-Cycle Hysteresis Loop Tracer for Small Samples of Low-Permeability Material. Wiegand, Hansen.....119–31; disc. 131
(Communication) Air-Borne Magnetometers for Search and Survey. Felch, Means, Slonczewski, Parratt, Rumbaugh, Tickner.....640–50
(Communication) An Electronic Regenerative Repeater for Teletypewriter Signals. Hearn..904–11
(Communication) An Improved Cable Carrier System. Black, Brooks, Wier, Wilson....741–6; disc. 746
(Communication) Applications of Rural Carrier Telephone System. Bartelink, Cook, Cowan, Mesmer.....511–17; disc. 517
(Communication) Bearing Deviation Indicator for Sonar. Schuck, Stedman, Hathaway, Butz.....1285–95
(Communication) Distortion and Band-Width Characteristics of Pulse Modulation. Krauss, Ordung.....984–8
(Communication) Distortion in a Pulse Count Modulation System. Clavier, Panter, Grieg.....989–1005; disc. 1005
(Communication) Frequency Division Techniques for a Coaxial Cable Network. Crane, Dixon, Huber.....1451–9
(Communication) Frequency Shift Telegraphy—Radio Radio and Wire Applications. Davey, Matte.....479–93; disc. 493
(Communication) Gas Pressure for Telephone Cables. Giese.....471–8
(Communication) Joint Use of Pole Lines for Rural Power and Telephone Services. Campbell, Hill, Moore, Schola.....519–24; disc. 524
Communication, Modulation in. Cowan.....792–6
(Communication) New Test Equipment and Testing Methods for Cable Carrier Systems. Tidd, Rosen, Wenk.....726–30
(Communication) Postwar Television Receiver Design. Pugsley.....453–8
(Communication) Pulse Code Modulation. Black, Edson.....895–9
(Communication) Pulse Echo Measurements on Telephone and Television Facilities. Abraham, Lebert, Maggio, Schott.....541–8; disc. 548
(Communication) Radio-Noise Influence of 230-Kv Lines. Norden.....677–81; disc. 682
(Communication) Rural Radiotelephone Experiment at Cheyenne Wells, Colo. Moore, Seyler, Wright.....525–8
(Communication) Some Modern Techniques in Ocean Cable Telegraphy. Cramer....494–500; disc. 500
(Communication) Submarine Detection by Sonar. Keller.....1217–30
Communication System, TVA Co-ordinated. Talmage.....1022–34; disc. 1034
(Communication) Television Equipment for Broadcast Stations. Lawrence.....443–52
(Communication) Television Network Facilities. Abraham, Rommes.....459–64
(Communication) The Application of Heterodyne Modulation to Wide-Band Frequency-Modulated Television Relays. Boothroyd.....1126–30
(Communication) The Application of Western Union Multiplex to Navy Radio. Hoover.....1478–82
(Communication) The Stromberg-Carlson XY Dial Telephone System. Reed.....432–8
Commutator Motor (Schrage Type), The Circle Diagram of the Polyphase Brush-Shifting. Franklin.....1667–72; disc. 1672
Comparison of Two Basic Servomechanism Types, A. Harris.....83–92; disc. 92
Comparison Testing Equipment to Fractional Horsepower A-C Stator Windings, The Application of Surge. Buchanan.....1356–8
Compass With Cathode-Ray Sensing Element, A Magnetic. Kliever, Syrdal.....529–34
Compensators, Metering With Transformer-Loss. Schleicher.....851–61; disc. 861
Complex Logarithmic and Geometric Mean Distances, Theory and Application of. Higgins.....12–16
Computation of Power Network Performance, Machine. Dunstan.....610–20; disc. 621
Computing Thermal Transients, Simplified Graphical Method of. Narbutovskih.....78–81; disc. 82
Conductor Effect on Sags in Suspension Spans, Broken. Bisiri, Landau.....1181–8
Conductors and a Method for Studying Them, Galloping. Tornquist, Becker.....1154–61; disc. 1161
Conductors, Effective Resistance of Isolated Nonmagnetic Rectangular. Dwight.....549–52

Considerations on High-Voltage Lines and Design Features of Tidd 500-Kv Test Lines, Corona. Wagner, Wagner, Peterson, Gross ..... 1583–90; disc. 1590
Constant-Current Motor Systems, Electronic. Livingston ..... 425–30; disc. 430
Constant-Frequency Generator, A Variable-Speed. Roys, Nader, Spotts ..... 1414–17; disc. 1417
Constants, Calculation of Sko. Puchstein ..... 1315–22; disc. 1322
Control and Power Systems for Aircraft Window Deicing. Mershon 1400–05
Control for Diesel-Electric Locomotives, Braking Resistors and. Weiser 229–32
Control for Latest New York Transit System Subway Cars, Motor. Riley 900–03
Control for Transport Airplanes, Automatic Temperature. Hedges 1197
Control, Functionalized Resistance Welding. Stadum, Large, Hartwig 414–18
Control of Air Switches for Line Sectionalizing and Load Transfer, Automatic. Rich, Kirwen ..... 293–9; disc. 299
Control of High-Speed Induction Motors, Adjustable Frequency. Heumann 719–25
Control of Hydroelectric Generating Stations, Automatic. Brown, Derr ..... 343–55; disc. 355
Control of Slip-Ring Motors by Means of Unbalanced Primary Voltages. Schmitz ..... 1103–1112; disc. 1112
Control of Switchgear, The Application of Storage Batteries to the. Hoxie ..... 1561–9; disc. 1569
Control of Thyratron Rectifiers, The Shunt Tube. Potter 421–4
Control, Radar Technique in an Industrial. Cockrell 269–72
Control System for A-C Crane Hoists, A Thrustor Lowering. Schwarz-Kast ..... 139–44; disc. 144
Control System for Aircraft D-C Generators, An Integrated. McClinton 94–8
Control System for Wind Tunnel Drives, A. Heidenreich ..... 1637–43; disc. 1643
Control Systems, Developments in Diesel-Electric Traction-Generator Excitation. Brancke, Adams ..... 223–8; disc. 228
Control Systems for Diesel-Electric Locomotives. Developments in. Henshaw 233–41
Control Systems, The Application of Lead Networks and Sinusoidal Analysis to Automatic. Schwartz ..... 69–76; disc. 76
Control, Theoretical Approach to Speed and Tie Line. Brandt ..... 24–9; disc. 29
Controlled Copper-Oxide Rectifiers for Electroplating and Anodizing Applications, Automatically. Buckley 181–4
Cooling of A-C Turbine Generators, Liquid. Pechheimer ..... 553–61; disc. 561
Co-ordinated Communication System, TVA. Talmage ..... 1022–34; disc. 1034
Copper-Oxide Rectifiers for Electroplating and Anodizing Applications, Automatically Controlled. Buckley 181–4
Copper-Oxide Rectifiers, Higher Voltage. Smith 220–2
"Copperspun" Squirrel Cage Rotor, The. Anderson 1312–14
Core Reactors, A Balanced Amplifier Using Biased Saturable. Kirachbaum, Harder 273–8
Cores, Interlaminar Eddy Current Loss in Laminated. Beiler, Schmidt ..... 872–7; disc. 877
Corona Considerations on High-Voltage Lines and Design Features of Tidd 500-Kv Test Lines. Wagner, Wagner, Peterson, Gross ..... 1583–90; disc. 1590
Corona Correction on Small Ceramic Bushings, High Altitude Flashover and. Pendleton 1324–30
Corona Discharges in Insulated Cables, Internal. Greenfield ..... 591–600; disc. 600
Corona Starting Voltages for Nonuniform Fields in Air, Determination of. Hutton ..... 1674–9; disc. 1680
Corps of Engineers, War Department, The Design and Performance of the Vertical Generator Thrust Bearings at the Bonneville Plant of the. Lewis, Gordon ..... 1231–7; disc. 1237
Correction on Small Ceramic Bushings, High Altitude Flashover and Corona. Pendleton 1324–30
Cotton Industry in the South, Electrification of the. Bobe ..... 201–08; disc. 208
Coupled Oscillograph Amplifier, Direct. Christian 1383–6
Coupling Method, A Simplified Double-Film Kydonograph With an Improved. Waghorne ..... 1114–16; disc. 1116
Crane Hoists, A Thrustor Lowering Control System for A-C. Schwarz-Kast ..... 139–44; disc. 144
Crest Voltmeters, The Calibration of Ignition. Davis, Warren ..... 99–104; disc. 104
Criteria of D-C Interrupters, Performance. Boehne, Jang ..... 1172–80; disc. 1180
Current at High Voltage, The Interruption of Charging. Leeds, Van Sickle ..... 373–80; disc. 381
Current Collectors for High-Speed Service, Developments in. Langer 51–4
Current into Rods, Tubes, and Flat Surfaces, Diffusion of Electric. Miller 1496–1502
Current Loss in Laminated Cores, Interlaminar Eddy. Beiler, Schmidt ..... 872–7; disc. 877
Current Measurements During Reignitions and Recovery, Circuit-Breaker. Lewis ..... 1253–7; disc. 1257
Current Motor Systems, Electronic Constant-. Livingston ..... 425–30; disc. 430
Current Transformers During Fault, Transient Characteristics of. Part II, Rothe, Concordia 731–4
Current, Transient Voltage Rise in Transformers Due to Interruption of Exciting. Srinivasan, Vogel 1632–6
Currents, Burning of Wood Structures by Leakage. Ross ..... 279–84; disc. 285
Currents in Disks, Driving and Damping Forces and Torques, Eddy. Moore ..... 1–10; disc. 10

D

Damping Forces and Torques, Eddy Currents in Disks: Driving and. Moore ..... 1–10; disc. 10
Data on the High-Frequency Resistance of Coils. Witzig 764–9
Deicing, Control and Power Systems for Aircraft Window. Mershon 1400–05
Demand Meter, A Polyphase Thermal Ampere-. Petringer 167–74
Design and Application of Supersonic Flaw Detectors. Erdman 1271–6
Design and Performance of the Vertical Generator Thrust Bearings at the Bonneville Plant of the Corps of Engineers, War Department, The. Lewis, Gordon ..... 1231–7; disc. 1237
Design, High-Voltage Power-Transformer. Part II. Mallett ..... 1086–91; disc. 1091
Design Method for Capacitor Motors, A. Lloyd, Chang ..... 651–7; disc. 657
Design Method for Capacitor Start Motors, A. Chang 1369–74
Design of Long-Scale Indicating Instruments, Advancements in the. Rowell, Millar 155–60
Design of New York Subway Motors for Dynamic Braking, The. Widell 808–10
Design, Postwar Television Receiver. Pugsley 453–8
Detection by Sonar, Submarine. Keller 1217–30
Detector Relay Protection, Typical Transformer Faults and Gas. Madill ..... 1052–8; disc. 1058
Detectors, Design and Application of Supersonic Flaw. Erdman 1271–6
Detectors for Use With Impedance Bridges, Electronic Null. Lamson 535–40
Determination of Corona Starting Voltages for Nonuniform Fields in Air. Hutton ..... 1674–9; disc. 1680
Determination of Magnetic Properties by Use of Cathode-Ray Oscilloscope, Quantitative. Zamsky 783–7
Development in Quebec, Hydroelectric Power. Lawton 1006–21
Development, Laboratory Aids for Electromechanical System. Newton, White ..... 315–19; disc. 319
Developments in Connection With Hot-Line Insulator Washing, Tests and. Hill 1203–16
Developments in Control Systems for Diesel-Electric Locomotives. Henshaw 233–41
Developments in Current Collectors for High-Speed Service. Langer 51–4
Developments in the PCC Car, Some Recent. Cooper ..... 288–92; disc. 292
Developments in Track Brakes and Drum Brakes for PCC Cars, Recent. Vouch 302–04
Deviation Indicator for Sonar, Bearing. Schuck, Stedman, Rathaway, Butz 1285–95
Device for Low-Voltage Circuit Breakers, An Improved Overcurrent Tripping. Kawlins, Sandin ..... 1149–53; disc. 1153
Diagram of the Polyphase Brush-Shifting Commutator Motor (Schrage Type), The Circle. Franklin ..... 1667–72; disc. 1672
Dial Telephone System, The Stromberg-Carlson XY. Reed 432–8
Dielectric Capacitors, The Probable Breakdown Voltage of Paper. Brooks ..... 1137–44; disc. 1144
Dielectric Heating—The Measurement of Loss Under Rising Temperature. Whitehead 947–9
Dielectric Properties of Cellulose Insulation Impregnated With Semiconducting Liquids, The. Clark ..... 55–62; disc. 62
Diesel Bus Where No Overhead Facilities Exist?, Can the Trolley Coach Compete Economically With the Gas or. Gaus ..... 264–8; disc. 268
Diesel-Electric Locomotive for the Seaboard Air Line Railway, A 3,000 Horsepower. Staples, Weybrew, Atwell 215–19
Diesel-Electric Locomotives, A Power Plant Regulating System for. Lewis ..... 242–6; disc. 246
Diesel-Electric Locomotives, Braking Resistors and Control for. Weiser 229–32
Diesel-Electric Locomotives, Developments in Control Systems for. Henshaw 233–41
Diesel-Electric Traction-Generator Excitation Control Systems, Developments in. Brancke, Adams ..... 223–8; disc. 228
Diffusion of Electric Current into Rods, Tubes, and Flat Surfaces. Miller 1496–1502
Dimensionless Analysis of Servomechanisms by Electrical Analogy. McCann, Herwald. Part I 111–18
Direct Coupled Oscillograph Amplifier. Christian 1383–6
D-C Aircraft Generator Power Center. Bottemiller 1267–70
D-C Generators, An Integrated Control System for Aircraft. McClinton 94–8
D-C Interrupters, Performance Criteria of. Boehne, Jang ..... 1172–80; disc. 1180
D-C Series Motor, Dynamic Braking of a Single. Leitch 149–54
Discharges, Field Research on Lightning Arrester. McCann, Beck ..... 625–9; disc. 629
Discharges in Insulated Cables, Internal Corona. Greenfield ..... 591–600; disc. 600
Disks: Driving and Damping Forces and Torques, Eddy Currents in. Moore ..... 1–10; disc. 10
Distance Relaying on 3-Phase Systems, Fundamental Basis for. Lewis, Tippett ..... 694–708; disc. 708
Distances, Theory and Application of Complex Logarithmic and Geometric Mean. Higgins 12–16
Distortion and Band-Width Characteristics of Pulse Modulation. Kraus, Ordung 984–8
Distortion in a Pulse Count Modulation System. Clavier, Panter, Grief ..... 989–1005; disc. 1005
(Distribution) Galloping Conductors and a Method for Studying Them. Tornquist, Becker ..... 1154–61; disc. 1161
Distribution in Textile Plants, Power. McConnell 659–62
(Distribution) Internal Corona Discharges in Insulated Cables. Greenfield ..... 591–600; disc. 600
(Distribution) Photographic Study of Lightning. Hagenguth ..... 577–83; disc. 583
(Distribution) Resistors for 138-Kv Cable Switching. Sadler, Blakeslee ..... 39–46; disc. 46
Division Techniques for a Coaxial Cable Network, Frequency. Crane, Dixon, Huber 1451–9
Double-Film Kydonograph With an Improved Coupling Method, A Simplified. Waghorne ..... 1114–16; disc. 1116
Drive for Aircraft, Electric. Crom 1359–62
Drives, A Control System for Wind Tunnel. Heidenreich ..... 1637–43; disc. 1643
Drives for Textile Finishing Ranges, Electric. Moore, Uhl 684–94
Drives, Rotating Stability Regulators for Synchronous Motor. Schaelchlin ..... 884–7; disc. 887
Driving and Damping Forces and Torques, Eddy Currents in Disks:. Moore ..... 1–10; disc. 10
Drop in the Welder Throat Loaded With Ferromagnetic Materials, The Voltage. Stein 356–62
Drum Brakes for PCC Cars, Recent Developments in Track Brakes and. Vouch 302–04
Dynamic Braking by Self-Excitation of Squirrel-Cage Motor. Srinivasan, Thomas 145–8
Dynamic Braking of a Single D-C Series Motor. Leitch 149–54
Dynamic Braking, The Design of New York Subway Motors for. Widell 808–10
Dynamic Brush Characteristics by the Dynamotor Method. Herman 759–63
Dynamometer for Small Motor Measurements, A High Precision. Duff ..... 1344–8; disc. 1348
Dynamotor Method, Dynamic Brush Characteristics by the. Herman 759–63

Preface

This 66th volume of the TRANSACTIONS of the American Institute of Electrical Engineers contains all approved technical program papers and related discussions presented at general meetings and District meetings during the calendar year, in accordance with the improved publication policy adopted by the board of directors at its May 1946 meeting.

The technical papers and discussions in the volume were presented at these meetings:

1. 1947 winter general meeting, New York, N. Y., January 27–31, 1947.
2. North Eastern District Meeting, Worcester, Mass., April 23–25, 1947.
3. Summer general meeting, Montreal, Que., Can., June 9–13, 1947.
4. Pacific general meeting, San Diego, Calif., August 26–29, 1947.
5. Middle Eastern District meeting, Dayton, O., September 23–25, 1947.
6. Midwest general meeting, Chicago, Ill., November 3–7, 1947.

In addition this volume contains:

1. 1947 annual report of the board of directors.
2. A complete listing of AIEE officers and committees for 1947–48.
3. New AIEE Publication Policy—Effective in January 1947.

Full correlation of all material in this volume has been accomplished by means of the multientry index beginning on page 1738. Reference to any of the several subject entries for a technical paper will lead directly to the paper and to any published discussion on that paper.

Statements and opinions given in papers and discussions published in TRANSACTIONS are the expressions of contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Eddy Currents in Disks: Driving and Damping Forces and Torques

A. D. MOORE
FELLOW AIEE

Synopsis: When two a-c fluxes, in quadrature, pass through a disk, driving forces and torques are produced. Theory is developed herein, and formulas and procedures are presented whereby the force or torque can be solved for, even when the fluxes are irregular as to area and distribution. As an example, the driving torque of a watthour meter is solved for. A chart for greatly facilitating the work is described.

When a constant flux (or fluxes) passes through a rotating disk, a damping or braking torque is produced. With the aid of what may be a new concept, theory, formulas, and procedures are presented whereby the torque may be found, even though the flux (or fluxes) has an irregular area. To illustrate, the damping torque of a watthour meter is computed. The method can deal also with fluxes of nonuniform density. A chart is described which greatly reduces the work.

When a disk with constant flux through it is moved translationally, damping forces occur. Curves covering a wide range are presented, by which those designing the damping for accelerometers and other instruments may design easily in direct fashion rather than by trial-and-error. For their benefit, this part of the paper is written so that it is complete in itself.

For both driving and damping torques, reciprocity laws are proved; when needed, these laws greatly reduce the time required for a solution.

It is often true that apparently complex devices can be analyzed with relative simplicity, whereas a simple-appearing device may require complex analysis. Eddy-current devices, structurally, are the simplest of electric mechanisms. Yet, because the eddy currents are not confined to easily identifiable paths, analysis has yielded scanty returns, and engineering design has limped along as best it could. This is true, even though some devices have been known for half a century or more; and speedometers and watthours, to name only two devices, are numbered in the millions. The literature of a basic character is notable for its paucity.

Lack of progress probably stems directly from an old difficulty, the usual tendency of analysts to proceed in terms of straightforward mathematics. The truth is that such methods simply cannot solve disk eddy-current problems in general. Irregular flux areas and densities can be handled practicably only by approximate methods such as are developed herein.

Conditions

As to a-c driving fluxes, this paper is limited to those cases in which disk resistance effect is large compared to disk reactance effect. As to damping fluxes, the paper is limited to cases in which the disk is thin enough, or velocity low enough, (or both) so that the eddy currents are not strong enough to have much effect in redistributing the flux. Meters and instruments usually meet these conditions.

The a-c driving flux treatment deals only with fluxes in quadrature. If actual fluxes are not in quadrature, only the quadrature components are effective in producing a net force.

A-C Driving Torques

A large thin metal disk, as in Figure 1, is pierced by fluxes Φ_J and Φ_K. These are the rms values of a-c fluxes, in quadrature. Such fluxes will be called a flux pair. Each is a uniform flux within a circle. The distance between circle centers J and K is S centimeters. The fluxes have a sine wave variation at frequency f. The circles do not overlap.

The variation of Φ_K sets up concentric eddies in quadrature with Φ_K. Eddy current maximum occurs when Φ_J is maximum. Φ_K eddies act on Φ_J to produce a sine squared wave of force. It will be shown that the average force, F_{KJ} in dynes, acting along JK or S, is

$$F_{KJ} = G/S \tag{1}$$

where G is developed further along.

The force F_{KJ} is actually a resultant force made up of an infinitude of forces, each due to an element of current reacting with the flux in the J-circle. The problem of finding the resultant can be avoided by resorting to a familiar analogous situation.

In the analogy, the two circles become sections of long parallel conductors normal to the paper. Conductor currents, I_J and I_K, are distributed uniformly. I_K sets up a concentric magnetic field. It long since has been shown

(*a*). That outside its conductor, the field due to I_K is the same as if I_K were centered (concentrated in a wire of infinitesimal section at K).

(*b*). That the force due to the distributed I_J reacting with the flux of I_K is the same as it would be if I_J were centered at J.

(*c*). The force per unit length for such a combination is proportional to $(I_J I_K)/S$.

From the analogy, it is clear that in our disk case, Φ_K can be centered at K, becoming a pencil of flux; Φ_J can be centered at J; and

$$F_{KJ} \propto \Phi_J \Phi_K / S \tag{2}$$

Development of G

In Figure 2, Φ_K has been centered, thereby becoming a flux pencil. In centering Φ_J, we have the privilege of moving it into the infinitesimal square, ds by ds, at J. The force originating in this square is F_{KJ}, and it now can be developed fully.

The effective voltage E developed by

Paper 47-1, recommended by the AIEE committee on basic sciences for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted July 9, 1946; made available for printing October 1, 1946.

A. D. Moore is professor of electrical engineering at the University of Michigan, Ann Arbor, Mich.

Φ_K in the disk (turns=1) and acting around the current ring of ds width is given by the familiar equation

$$E=2\pi f\Phi_K\times10^{-8} \tag{3}$$

To find R, the resistance of the current ring,

ρ = disk resistivity, ohm per centimeter
b = disk thickness, centimeters
$2\pi S$ = path length
bds = path section

$$R=\frac{\rho 2\pi S}{bds} \tag{4}$$

To find the rms current of the ds by ds square

$$I=\frac{E}{R}$$
$$=2\pi f\Phi_K\times10^{-8}\div\left(\frac{\rho 2\pi S}{bds}\right)$$
$$=\frac{fb\Phi_K\times10^{-8}}{\rho S}ds \tag{5}$$

The dynes force is given by the familiar form, $BIL/10$. In the ds by ds square, $B=\Phi_J/(ds)(ds)$, I is given by equation 5, and L is equal to ds. The force is then

$$F_{KJ}=\left[\frac{\Phi_J}{(ds)(ds)}\right]\left[\frac{fb\Phi_K10^{-8}}{\rho S}ds\right]\left[ds\right]\frac{1}{10}$$
$$=\frac{fb\Phi_J\Phi_K\times10^{-9}}{\rho S} \tag{6}$$

Let

$$G=\frac{fb\Phi_J\Phi_K\times10^{-9}}{\rho} \tag{7}$$

$$F_{KJ}=\frac{G}{S}\text{ dynes} \tag{1}$$

Because this force is the product of two effective values, and because the current and flux concerned are in phase, the force F_{KJ} is the time average of the actual force.

Torque

The torque T_{KJ} (see Figure 1) due to force F_{KJ} acting at lever arm D about some point O, in dyne-centimeters, is

$$T_{KJ}=F_{KJ}D$$
$$=G\frac{D}{S} \tag{8}$$

Reciprocity Law and Torque of a Flux Pair

It is obvious that in addition to F_{KJ}, there is an equal force F_{JK}, due to J-eddies acting on Φ_K. Thus there is a reciprocity law as to forces. The total force is the sum of the two. Thus, for a flux pair (either in nonoverlapping circles or as pencils) the total, F_p, is

$$F_p=2\frac{G}{S} \tag{9}$$

As to torque, both forces act with lever arm D. Thus there is a torque reciprocity law. Then the total torque T_p for a flux pair is

$$T_p=2G\frac{D}{S} \tag{10}$$

Circular Disk

If an a-c flux pencil at K, Figure 3, pierces a circular disk of radius A centimeters, the eddy currents occur in eccentric circles. Morton[1] gives the equation for the eccentricity. It is not included here, because a simplification used herein consists of avoiding the problem of dealing with eccentric current paths. The image concept is resorted to.

On a very large plate or disk, Figure 3, lay out the disk circle as shown. Extend OK. The image of the K-pencil of flux can be located at K', by theory long since developed. If $OK=R$,

$$KK'=(A^2-R^2)/R$$
$$OK'=KK'+R$$
$$=\frac{A^2-R^2}{R}+R$$
$$=\frac{A^2}{R} \tag{11}$$

The image or K'-pencil is equal to the K-pencil but is opposite in sign. Acting together, this pencil pair will set up the double eccentric eddy pattern; and within the disk circle, the eddies are identical with what the K-pencil alone would set up in the real disk.

Passing to Figure 4, we avoid eccentricity troubles by dealing with the flux pencils individually. In the large disk, the K-pencil sets up component concentric eddies about itself; and likewise, for the K'-pencil. (Note that this pair within itself creates no net force; the eddies of each are in quadrature with the flux of the other.)

The foregoing is applied in Figure 5, where a disk is acted on by a flux pair. The flux Φ_K can be centered first at K. The K-pencil image at K' is located next. The flux pair creates a total force as expressed in equation 9 and a total torque as given by equation 10. Similarly, the flux pair Φ_J and $\Phi_{K'}$ yield another (smaller) force and torque, the force acting along S' at lever arm D'. Since the image flux is opposite to the K-pencil, the image torque opposes the direct torque; and the net torque is

$$T_p=2G\left(\frac{D}{S}-\frac{D'}{S'}\right) \tag{12}$$

Figure 1. Large disk and flux pair

Figure 2. Force, centered fluxes

Figure 3. Flux pencil, image, and eccentric eddy-current pattern

General Torque Expression: Circular Disk and a Flux Pair

To develop a general torque expression, we will use the additional constructions given in Figure 5. Instead of lever arms D and D', lever arm $C=OJ$ will be used. This calls for the use, not of the whole forces along S and S', but of their horizontal components (taking C as vertical). The components are H/S and H'/S', respectively, times the two forces. The total torque can be written then

$$T_p=2G\left(\frac{C}{S}\frac{H}{S}-\frac{C}{S'}\frac{H'}{S'}\right)$$

$$=2GC\left(\frac{H}{S^2}-\frac{H'}{S'^2}\right) \tag{13}$$

In equation 13, H, H', S^2, and S'^2 can be replaced as follows: if θ is the angle between C and R

$$H=R\sin\theta$$

$$H'=\frac{A^2}{R}\sin\theta$$

Using the cosine law of triangles

$$S^2=C^2+R^2-2CR\cos\theta$$

and

$$S'^2=C^2+(A^2/R)^2-2C(A^2/R)\cos\theta$$

$$T_p=2GC\left[\frac{R\sin\theta}{C^2+R^2-2CR\cos\theta}-\frac{(A^2/R)\sin\theta}{C^2+(A^2/R)^2-2C(A^2/R)\cos\theta}\right] \tag{14}$$

$$=2G\left[\frac{\sin\theta}{(C/R)+(R/C)-2\cos\theta}-\frac{\sin\theta}{(CR/A^2)+(A^2/CR)-2\cos\theta}\right] \tag{15}$$

$$=G\left[\frac{\sin\theta}{\frac{1}{2}\left(\frac{C}{R}+\frac{R}{C}\right)-\cos\theta}-\frac{\sin\theta}{\frac{1}{2}\left(\frac{CR}{A^2}+\frac{A^2}{CR}\right)-\cos\theta}\right] \tag{16}$$

If J and K are equidistant from O, $C=R$, and the torque reduces to

$$T_p=G\left[\frac{\sin\theta}{1-\cos\theta}-\frac{\sin\theta}{\frac{1}{2}\left(\frac{C}{A}\right)^2+\frac{1}{2}\left(\frac{A}{C}\right)^2-\cos\theta}\right] \tag{17}$$

Variation of Disk Torque With Flux Pair Radius

Let the a-c driving fluxes of a circular disk consist of a flux pair at the same radius ($C=R$). Either circle may be of any size. However, the circles may not overlap, nor may they fall partly outside the disk, if the equations are to hold. If θ is taken constant at 30 degrees, for example, a curve of torque versus C for a disk of fixed A can be worked out. This curve, for $G=1$ (for example, when $f=60$, $b=0.0915$, $\Phi_J=\Phi_K=22.7$ maxwells, and $\rho=2.83\ (10)^{-6}$, G is unity) is shown in Figure 6 in terms of T_p versus C/A. The trends of this curve are interesting.

As C approaches A, the images move in closer to the disk circle and have an increasing negative torque effect.

As the flux pair is made to retreat from the disk edge, the images move out and diminish in effect, and the net torque increases. But as C is reduced further, one is tempted to conclude that since low C means low lever arm, the torque would fall off again. But it must be remembered that under the conditions, S is proportional to C, and that eddy current strength, for example, caused by Φ_K through J, is inversely proportional to S. Therefore, torque will not fall off. Inspection of equation 17 shows that as C/A approaches zero, T_p approaches a constant value. The achievement of greatest torque at least possible radius may be somewhat surprising.

Figure 5. Torque of a flux pair

Figure 4. Concentric eddy currents caused by individual flux pencils

Disk Torque Due to Irregular Fluxes

Disk driving torque can arise due to two fluxes in quadrature, neither flux being contained within a circular area and both having irregular density distribution. Moreover, the fluxes may overlap greatly. The watthour meter presents just such a problem. A feasible method for finding the torque will be developed now.

The area where a flux pierces the disk can be divided into a number of rectangular areas, each containing a known amount of flux. The other flux is treated likewise. In each little area, the flux of that area is centered arbitrarily; it becomes a flux pencil located somewhere within the area. Any error thus introduced will be treated later. If the two fluxes are Φ_J and Φ_K, every J-pencil's eddies must be allowed to react with every K-pencil; also (for the images) every J'-pencil must be allowed to react with every K-pencil; and a summation must be arrived at somehow. The amount of work involved in the solution could be great, if carried out in terms of equation 14 or equation 15.

Figure 6 (left). Variation with radial position of torque of an equal-radius flux pair, G being unity

Figure 7 (right). The D/S chart

Instead of using these general forms, it is much faster to retreat to the form of the torque as given in equation 10. The case can be drawn to scale, D, S, D', and S' values can be measured directly, and the computing can be done by using a slide rule. Even so, the fairly accurate treatment of a watthour meter would call for many measurements and a good deal of slide rule work. The writer therefore devised a labor-saving chart.

The D/S Chart

Figure 7 shows a limited portion of a D/S chart. It is of very simple construction, composed of a centimeter grid and radial lines, the location of which will be obvious after a little study. The chart is put on tracing cloth.

In use, a pencil J is to react with another pencil K to produce a component torque about O. (Steps are shown on the chart by circled numbers.)

Step 1. The chart is placed on the drawing with apex over J.

Step 2. The chart axis is made to pass through K.

Step 3. Note where the disk center O is.

Step 4. Move parallel to the axis from O until opposite K.

Step 5. Read the D/S value of the slant line through the last point found, or interpolate as may be necessary.

After determining the G-value pertaining to the particular flux strengths of the two pencils, equation 10 will give the torque of the pencil pair. Further procedures can be brought out best in the watthourmeter study.

Driving Torque of a Watthour Meter

The theory and methods presented have been given a thorough trial by the writer's application of them to a Duncan watthour meter rated 5 ampere, 115 volt, single-phase, 60 cycle, type MF-A. The processes and results will be given here in condensed form. The meter chosen is the one so ably described by Green.[2] For more complete data than can be given here, see his paper. Green gives the nominal torque as 46 gram-millimeters at 575 watts. But this was for a 5-spoked disk. Later, a solid disk was adopted which, according to information obtained from the company, raised the nominal torque to 51. For the aluminum disk, A is 4.45 centimeters (3.5 inches), and b is 0.0915 centimeter.

Figure 8 shows the core parts essential to the job of mapping the important regions of the driving fluxes. The writer graphically mapped the fluxes. At the right (Figure 8) half the potential flux is mapped. The other half of the potential flux (not shown) duplicates on the left the right half. At any one instant, both halves are either up or down.

At the left (Figure 8) the series flux is mapped. At an instant when this flux is upward at the left, the same flux (not shown) would be downward at the right. Looking ahead to Figure 9, it is seen that the fluxes have been cut up into certain small rectangular areas. The means of doing this and the computing of flux quantities must be outlined briefly. For field mapping techniques, one may refer to Moore.[3]

Potential Flux

Consider the flux in a path in the map of Figure 8, such that the path is defined by any curvilinear square and an axial dimension (into the paper) of one inch. It can be shown that the reluctance in air is such that one ampere-turn acting on the reluctance will set up 3.19 maxwells of flux.

The potential coil furnishes 162 rms ampere-turns. The core's axial dimension is 0.60 inch. A tube, as mapped, has two curvilinear volumes in series. The flux per tube is then $(3.19\times162\times0.60)/2=155$ maxwells. Counting from the center at t to as far as x, the span tx takes in 4.4 tubes. Weak flux beyond x was omitted. The points u, v, and w were spotted in then so that the spans tu, uv, vw, and wx each contains 1.1 tubes, or $(1.1\times155)=170$ maxwells. In Figure 9, the axial dimension was divided into four equal parts. We thus have divided the right potential flux into 16 parts, each containing $(170\div4)$ or 42.5 maxwells.

These fluxes must be centered, and this must be done with care. The only problem is in the centering locations in the tx direction. In Figure 8, the points marked *1*, *2*, *3*, and *4* were spotted in by reading the map in order to place these not halfway along tu, uv, and so forth but at mid-flux positions.

There are also 16 similar potential flux areas to the left (Figure 9).

Series Flux

There are 60 rms ampere-turns on each gap, setting up the series flux. Flux per tube is then $(3.19\times60\times0.6)/2$, or 57.5 maxwells. The series flux included in this study (left, Figure 8) reaches

Figure 8. Watthour-meter flux map

from t to z, taking in 6.1 tubes. Weak flux beyond z was omitted.

If we now divide the series flux so as to cut it into rectangles of equal flux amounts, this advantage is gained: G will be the same for any pair. But there is a worse disadvantage. Some potential rectangles will overlap partially some series rectangles, and special problems will be created. An alternative was adopted. The potential pattern of rectangles was laid over the series map (t, u, v, w, left) and the differing amounts of series flux in each span were read from the series map. The remaining series flux falls in the spans xy and yz, and two more series flux values were read off there. These two were centered at *5* and *6*.

By this scheme, the potential and series rectangles fall into two classes: (1) they are separated or, at closest, merely touch; (2) or, where they overlap they completely coincide and drop out of consideration.

The series flux is divided thus into six unequal tube fractions, these being 0.65, 0.95, 1.2, 1.4, 0.9, and 1.0, reading from t to z. At 57.5 maxwells per tube, these amount to 37.3, 54.6, 69.0, 80.5, 51.7, and 57.5 maxwells. After dividing the 0.6 inch dimension into four equal parts as before, the series rectangles have fluxes (same order) equal to 9.33, 13.65, 17.25, 20.1, 12.91, 14.38.

Values of G

All potential fluxes are alike, 42.5 maxwells. But there are six series flux values. Using them, and $f=60$, $b=0.915$, $\rho=2.83\ (10)^{-6}$ for aluminum at 20 degrees centigrade, the six G-values obtained are 0.767, 1.12, 1.416, 1.651, 1.06, and 1.18.

Organization

The areas in Figure 9 have been identified in terms of lettered rows (A, B, C, D) and numbered columns (1, 2, 3, 4, 5, 6). Any area with any letter and any number from 1–4 contains 42.5 maxwells of potential flux. As to series flux, in either half, $A1$ and $C1$, as examples, contain 9.33 maxwells; whereas, $D6$ has 14.38 maxwells.

Images

After centering the fluxes, the left potential pencils were imaged, and the images identified by primes (Figure 9).

It was not necessary to use series flux pencil images, because the reciprocity law takes care of their effects in the equations already written for torque.

Routine

Suppose the right potential $A1$ pencil is allowed to react with all the left series pencils, one by one. The apex of the D/S chart is placed over the $A1$ pencil and held there by a needle point. The chart then is swung about easily. The axis is moved over a left series pencil. The routine described quickly leads to recording a D/S value. The work of multiplying each value by $2G$ is saved by organizing properly the tables for recording D/S. Only the sum of appropriate D/S values need be multiplied by its proper $2G$. The results of four sets of operations must be set down here.

Torques as Found

Left potential fluxes acting on right series fluxes gave a torque of 1,513 dyne-centimeters, which includes reciprocity. However, an equal torque comes from right potentials acting on left series. The total is then 3,026.

Left potential images with right series gave 450. This is doubled also, yielding a total of 900, which acts negatively. Summing up so far, the net torque is 3,026−900, or 2,126.

It is usual to explain the driving torque of the watthour meter in terms of the actions of fluxes that are separated distinctly. The torque found so far comes from such fluxes. But this meter has a torque of 51 gram-millimeters; and the torque found above, 2,126, amounts only to $(2{,}126\times10)/981=21.7$ gram-millimeters. This is less than half the needed amount.

But more torque can be found, and from sources perhaps heretofore neglected. In considering left potential and left series flux, it has been invitingly easy to

Figure 9. Watthour-meter flux rectangles, centerings, and potential images

Figure 10. Flux band and pencil pair

jump to the conclusion that because these two fluxes are approximately alike and roughly superimposed, they can produce little torque, if any; likewise, for right potential and right series. But the facts are surprising. There is a fair amount of cancellation where the two areas of a pair are identical in position; and there is a good deal of negative torque where a pair teams up to act the wrong way. In spite of all that, left potential with left series yields a torque of 1,152 which, doubled, gives a total of 2,304. Left potential images with left series give 145 which, doubled, gives a total negative of 290. The net torque thus additionally found is 2,304−290=2,014, which is just about equal to the 2,126 already found. Two fluxes "approximately alike and roughly superimposed" had better not be neglected!

The total then is 2,126+2,014=4,140 dyne-centimeters, or 42.2 gram-millimeters.

Predicted Versus Actual Torque

The Duncan meter has an overload plate made of laminations. It partly surrounds the tops of the series poles. Its purpose is to correct the inherent overload droop in the accuracy curve, caused by series flux damping effect. The construction and theory of the plate do not concern us here. However, the plate somewhat changes the amounts and distributions of the driving fluxes and, according to Green, serves to increase the torque by seven per cent when the plate is introduced. Our predicted torque then becomes 1.07×42.2, or 45 gram-millimeters.

The predicted torque of 45 is 12 per cent below the 51 nominal torque.

An exact check would not be too meaningful unless a very complete and careful study were made of a particular meter. This in part is true because of variations of meters in production caused by allowable variations of air gaps, characteristics of iron, and so on. It is not necessary for meters to be exceedingly close duplicates as to driving torque, because there is a good range of adjustment of damping flux for securing accuracy in the calibration process. Other reasons for failing to check exactly will be taken up now in discussing sources of errors.

Errors in the Method

There are three sources of error in the foregoing procedure.

Centering Noncircular Flux. In a flux pair, uniform flux in a circle is centered without error. But error results when uniform rectangular flux is centered. For parallel rectangles, Dwight[4] conveniently furnishes the correction under another guise, forces between parallel strap conductors. In the meter, the worst error occurs for the adjacent areas $A2$ and $A3$, $B2$ and $B3$, and so forth. The uncorrected force found by centering is about 25 per cent high. But most of the other adjacent flux pairs have a much smaller error. For example, for adjacent squares, force found by centering is only two per cent high. It is the writer's opinion that the total predicted torque is only two or three per cent high, attributable to centering error.

Nonuniform Density. The centering error was concerned with uniform density. Another error arises due to nonuniformity of density. Remember that potential flux was mid-flux centered; but that in rectangles 1–4, series flux was centered arbitrarily at these same potential centers. This is convenient but erroneous, because the two fields are not identical in distribution. The writer's opinion is that the nonuniformity error in the meter study is only two or three per cent, on the low side. Thus the two errors so far discussed may nearly nullify.

2-Dimensional Treatment. The map of Figure 8 is a 2-dimensional map, drawn as if the axial dimension were great. Actually, this dimension is only 0.60 inch. Since the shortest gap is nominally 0.125 inch, it is certain that there is a good deal of useful fringing flux both inside (radially) and outside of the limits shown in Figure 9. The actual distribution would give weaker fluxes than those allowed to the A and D levels but also additional flux outside the A-level and inside the D-level.

The error due to using the 2-dimensional map and omitting fringing (and also omitting weak fluxes beyond x and z) easily could account for all of the difference between predicted and actual torques.

Possibilities

In a device, if the flux distributions were determined actually by measurement and were used in a study no more detailed than that used for the meter, forces or torques should be predicted with an over-all error of no more than five per cent.

A less detailed study, using only a few

Figure 11 (left). J-pencil acting on part of area 2, polarities

Figure 12 (right). Alpha chart for $\alpha=20$ degrees

Figure 13. Damping reciprocity law

rectangles and capable of solution in a relative short time, will yield reasonably good values of torque.

In the meter study, the work with the chart, the summing up, and the computing of torque requires about eight hours. This does not include time for drawing and flux mapping.

Damping Forces and Torques

An electromagnet or a permanent magnet puts a flux, uniformly distributed and of density B, through a circular rotating disk, within the area shown in Figure 10. The area has any size and shape. There may be more than one area, each with its own density.

The description of the Foucault currents caused by rotation, and the finding of resulting forces and torques heretofore have not been attacked successfully for such general cases. Solutions can be achieved by means of what is believed to be a new concept, by the use of some of the a-c developments already described and of some developments yet to be mentioned.

Flux Band and Pencil-Pair Concept

The flux can be divided into bands, each of constant radius and narrow width, such as band JK in Figure 10. Radial elements of metal sweep through the flux of the band and set up a constant electromotive force around any such paths as path 1 and path 2

Figure 14. Watt-hour meter damping

The concept referred to above is this: the same electromotive force can be set up around such paths in a *fixed* disk by means of pencils of flux piercing the disk at J and K, these being opposite flux pencils, and both increasing or decreasing at the same rate. Adoption of this concept makes it possible to define the currents set up by the JK flux band and by all other such bands. The concept of fixed-disk-and-pencil-pair is used only to to define the currents. The currents are allowed then to react with the actual flux in order to find forces and torques.

The adoption of the changing pencil pair makes it possible to adopt the image and concentric current ideas already fully outlined in the a-c developments.

Force Due to a Pencil, and Flux in an Angle

In Figure 11, there are two flux areas, area 1 and area 2, with densities B_1 and B_2. A narrow flux band JK at radius r in area 1 is replaced for current effects by flux pencils J and K changing through a fixed disk. As in previous developments, J has its (opposite) image pencil J', and K has its (opposite) image pencil K'. We then have four flux pencils through a large disk, each setting up concentric eddies about itself. The resultant of these four current patterns would be identical within the disk circle, with the actual current set up in the rotating disk by the JK flux band. Such of these concentric currents as pass through the areas will react with B_1 and B_2 to produce forces.

Throughout, we may think either of the flux pencils as all constantly increasing or as decreasing. Herein, they will be treated as decreasing. With rotation as shown in Figure 11, and with downward B_1 flux, the electromotive force due to flux band JK would be outward. Then the four pencils would have signs as shown in Figure 11*b*, and they would set up currents as shown. These currents are such as would tend to prevent the (decreasing) change of the flux pencils.

The flux band electromotive force due to rotation, in volts per radial centimeter, is

$$E = \omega r B_1 \times 10^{-8} \tag{18}$$

ω is angular velocity in radians per second.

Ascribing this electromotive force to flux pencils in a fixed disk, we now find the current element di of width ds, flowing concentrically about J at radius S from J. The resistance R offered to di is given by equation 4. Then

$$di = \frac{E}{R}$$
$$= \frac{bEds}{\rho 2\pi S}$$

Consider the resultant dynes force df

Figure 15. Nonuniform flux

caused by the di current arc within the angle α (see Figure 11). It is shown easily that the force due to the current arc is the same as if the current flowed along the chord. By symmetry, the force acts through J.

$$\text{Chord} = 2S \sin \frac{\alpha}{2}$$

$$F = (BIL)/10 \text{ dynes, in general}$$

$$df = 0.1 B_2 2S \sin \frac{\alpha}{2} \cdot di$$

$$= \left(0.2 B_2 \sin \frac{\alpha}{2}\right) S \frac{bEd}{\rho 2\pi S}$$

$$= \left(0.1 B_2 \sin \frac{\alpha}{2}\right) \frac{bE}{\pi\rho} ds \qquad (19)$$

Let F_a in dynes per centimeter of r designate the forces due to J-currents acting on B_2 flux contained within the area bounded by arcs of radius S_1 and S_2, and angle α.

$$F_a = \int_{s_1}^{s_2} df$$

$$= \left(0.1 B_2 \sin \frac{\alpha}{2}\right) \frac{bE}{\pi\rho} \int_{s_1}^{s_2} ds$$

$$= \left(0.1 B_2 \sin \frac{\alpha}{2}\right) \frac{bE}{\pi\rho} (S_2 - S_1) \qquad (20)$$

If OJ (equal to radius r) is taken vertically, we need the horizontal component of F_a which, acting through J on lever arm r or OJ, produces torque about O. The horizontal component, F_{aH}, is

$$F_{aH} = \cos \beta \cdot F_a$$

$$= \left(\sin \frac{\alpha}{2}\right) \left[(S_2 - S_1) \cos \beta\right] 0.1 \frac{bB_2E}{\pi\rho}$$

$$= \left(\sin \frac{\alpha}{2}\right) \left[(S_2 - S_1) \cos \beta\right] 0.1 \frac{bB_2}{\pi\rho} \omega r B_1 \times 10^{-8}$$

$$= \left(\sin \frac{\alpha}{2}\right) \left[(S_2 - S_1) \cos \beta\right] \frac{\omega r b B_1 B_2 \times 10^{-9}}{\pi\rho} \qquad (21)$$

To abbreviate, let $M = \sin \alpha/2$, $n = [(S_2 - S_1) \cos \beta]$, w' = the fraction.

$$F_{aH} = Mnw' \qquad (22)$$

Integration of Horizontal Forces: The "Alpha" Chart

Some means of integrating over the whole of area 2 must be found. For this, the writer devised the "alpha" chart, shown in Figure 12, this example being drawn for $\alpha = 20$ degrees, $M = 0.1736$. In the a, b, c, d area, it will be evident that n, or $[(S_2 - S_1) \cos \beta]$, can be read directly from the vertical parallels spaced one centimeter apart, when the main line of the chart is lined up through disk center O and chart apex is placed at pencil J. In this example, $n = 6.9 - 2.4 = 4.5$.

The total horizontal force F_H due to J-currents through Φ_2 in area 2 would be (approximately) proportional to the sum of the several F_{aH} values. Let

$$N = \Sigma n \qquad (23)$$

In the example, start at point p, proceed clockwise around the perimeter of area 2, and read off successive values.

$$N = (5.2 + 6.9 + 7.7 + 5.3) - (3.1 + 2.5 + 2.4 + 2.5)$$

In general

$$F_H = MNw' \text{ dynes per centimeter of } r \qquad (24)$$

In practice, several "alpha" charts are needed, with α ranging from small to large. By selecting the right chart to use on a near or far area, the area can be sliced always into enough sectors to insure high accuracy with minimum time spent at reading and summing up. The summing is done most easily by putting the readings directly onto the adding machine.

The less accurate readings are likely to be achieved where the radial lines soon leave after entering the area, as at ee in Figure 12. In such cases, a correcting mental estimate is easily made. In general, the errors of this approximate chart method tend to cancel out, and high accuracy is achieved.

Torque: One Flux Interacting With Another

If T_r in dyne-centimeters per centimeter of r is the torque due to F_H acting at lever arm r (or OJ), then

$$T_r = F_H r$$

$$= MNw'r$$

$$= MN \frac{\omega b B_1 B_2 \times 10^{-9}}{\pi\rho} r^2 \qquad (25)$$

Let

$$W = \frac{\omega b B_1 B_2 \times 10^{-9}}{\pi\rho}$$

$$T_r = MNWr^2 \qquad (26)$$

Appropriately select several different radii from inner radius R_i to outer radius R_o, and find MNr^2 for each. This work is routinized and carried out in tabular form with the aid of "alpha" charts. W is common throughout and should be omitted until the tabulations are added up.

Plot a curve of MNr^2 versus r. Find the mean ordinate and call it T_A. Then, if Ij in dyne-centimeters is the torque due to all J-pencils on the J-side of area 1,

$$T_J = T_A(R_o - R_i)W \qquad (27)$$

Figure 16. Translational damping

T_K is found likewise for all K-pencils on the K-side of area 1. The torque due to the image-pencil's currents requires a different treatment, because the forces act through the images. For the J' image,

$$T_r = (OJ')F_H$$

$$= MNw'(OJ') \qquad (28)$$

N is found by now centering the "alpha" chart apex at J'. As previously shown in equation 11, $OJ' = A^2/r$. Then

$$T_r = MN \frac{\omega r b B_1 B_2 \times 10^{-9}}{\pi\rho} \frac{A^2}{r}$$

$$= MN \frac{\omega b B_1 B_2 \times 10^{-9}}{\pi\rho} A^2$$

$$= MNWA^2 \qquad (29)$$

For the same several radii from R_i to R_o as used before, MNA^2 is found and plotted. T_A is obtained, and

$$T_J' = T_A(R_o - R_i)W \qquad (30)$$

T_K' is found likewise.

All four torques are combined then to get the net torque T_{12}, expressed positively as a braking torque; thus

$$T_{12} = T_K - T_J - T_K' + T_J' \qquad (31)$$

The routine above was presented in order to make the analysis easily understood. However, it requires plotting four curves. This can be avoided by combining, in the tabulation of data, the MNr^2 and MNA^2 values (four in all for each r used) and then plotting only one curve and finding only one T_A from it.

T_{12} is the torque due to all currents originated by area 1, acting on the flux of area 2.

Reciprocity Law

It will be shown next that here again a reciprocity law holds. As far as the writer knows, this law has not been proved heretofore. In Figure 13, let flux bands J_1K_1 and J_2K_2 each subtend

the small angle $2\Delta\lambda$ and each be Δr radially. Their centers, where $\Delta\Phi_1$ and $\Delta\Phi_2$ can be centered for force purposes, subtend the angle λ. Current due to pencils J_1 and K_1 act on $\Delta\Phi_2$ to give two forces; J_2 and K_2 act on $\Delta\Phi_1$, giving two more forces. Four forces and torques are involved. Force $J_1\Delta\Phi_2$ is proportional to $\Delta\Phi_1\Delta\Phi_2$. Force $K_2\Delta\Phi_1$ is proportional to $\Delta\Phi_2\Delta\Phi_1$. These flux products correspond to G of equation 16 which, aside from constants, is a flux product. The bracket of equation 16 takes care of the geometry (including images) to find the torque of a flux pair. The value of the bracket will be the same for both forces, since C and R are common, and θ is $\lambda+\Delta\lambda$ for each. Therefore, torque $J_1\Delta\Phi_2$ equals torque $K_2\Delta\Phi_1$. Likewise, torques $J_2\Delta\Phi_1$ and $K_1\Delta\Phi_2$ are equal, θ now being $\lambda-\Delta\lambda$ for each. A reciprocity law therefore obtains for the flux bands, and if the incremental values are taken as infinitesimals the proof is rigidly correct. Next, any area 1 or area 2 can be built up of such bands. That which is true for the parts will be true for the wholes. Then the total torque due to two flux areas is (except for self-torques)

$$T=2T_{12} \tag{32}$$

Self-Torque

Each area of course also produces torque on a self basis, its own eddies acting on its own flux. The same general procedure holds for finding it. With chart apex at J, for instance, the chart is read around the boundary of area 1.

When there are two flux areas, the self-torques are in general larger, and often much larger, than the interaction torque.

Torque Due to One Circular Area of Flux

Smythe[5] gives an accurate equation for torque due to disk rotation through a single circular area of flux. A case was selected as follows:

$A=13$ centimeters
Flux circle radius $=2.5$ centimeters
$C=10$ centimeters
$\omega=1$
$b=0.1$ centimeter
$B=1{,}000$
$\rho=2.83\ (10)^{-6}$

For this case, the accurate torque (Smythe equation) is 27,000 dyne-centimeters. By the methods presented here, and using only five radii aside from R_1 and R_n, we get 27,200. The use of "alpha" charts involves graphical methods, and so the difference is even smaller than might be expected.

Watthour-Meter Damping Torque

The methods were given a full trial by predicting the damping torque of a Duncan watthour meter. The alnico magnet poles are below the disk; the armature is above. In Figure 14, 1 is the perimeter of a pole face. Flux as measured by ballistic galvanometer and search coil 2 was 2,400 maxwells. Flux measured through search coil 3 was 3,000 maxwells. For computing torque, the arbitrary area 4 was adopted, along with the assumption that it carries 3,000 maxwells at uniform density. At the right, in Figure 14, the area 4 is shown, and the arcs show the radii of flux bands used in the solution. The images are not shown. The time required for the solution, including making the drawing, locating the pencils, using the "alpha" charts, tabulating and adding data, and finding T_A and T, was about five hours.

The damping torque was computed for these conditions,

$\omega=3.02$ (being for 575 watts, 28.75 rpm)
$b=0.0915$
$\rho=2.83\ (10)^{-6}$
Predicted torque $=48.5$ gram-millimeters
Meter's nominal torque $=51$

In view of the arbitrary treatment given the flux, and the neglect of flux outside of area 3, the close agreement must be considered somewhat fortuitous.

Nonuniform Flux Distribution

These methods can be extended to handle flux areas having any flux distribution. Contour lines would be drawn within the area, and between successive contour lines the density would be considered constant. As a simple example, Figure 15 shows a case having only two contour lines. The easiest treatment is secured by letting B_1 cover the entire area, whereupon the inner area has the additional component (B_2-B_1). Pencils J_1 and K_1 are then caused by B_1. Pencils J_2 and K_2 are attributable to (B_2-B_1). J_1 and K_1, via the "alpha" chart, act on the entire area of B_1 density and also on the inner area of (B_2-B_1) density. Pencils J_2 and K_2 likewise react on both areas. Most damping fluxes come from permanent magnets. In nearly all such cases, the flux distribution will not be known with enough certainty to warrant more than a 2-contour treatment, if that.

Translational Damping

Accelerometers and other instruments often are damped by means of a disk-and-magnet combination, the relative movement being translational. The problem involves forces only, not torques. Otherwise, the "alpha" charts and the routines already described are applied readily. A reciprocity law obtains, but the proof is omitted; anyone able to follow the proof for the rotational reciprocity law can prove easily the translational law.

Many of those concerned with instrumentation heretofore have had to meet their damping needs by rather blind trial-and-error work. The writer therefore has worked out a series of cases, leading to a family of curves. These curves enable intelligent design to be carried out in a very simple fashion.

In Figure 16, two opposite fluxes pierce the disk in parallel rectangles. The motion is horizontal. Using the dimensions (centimeters) as indicated, first find the dimensionless ratios X and Y, where $X=P/D$ and $Y=H/D$. Take these to the curves of Figure 17 and find F'. Next compute W. If

$V=$ velocity, centimeters per second
$b=$ disk thickness, centimeters
$\rho=$ disk resistivity, ohm per centimeter (for aluminum at 20 degrees centigrade, $2.83\ (10)^{-6}$)
$B=$ gausses (maxwells per square centimeter)

$$W=\frac{VbB^2\times10^{-9}}{\pi\rho}$$

Then

$$F=WD^2F' \tag{33}$$

To derive the curves the writer computed for Y-values of one, two and four,

Figure 17. F' curves for translational damping

and several values of X. The curves for Y of one, two, and four are correct, it is believed, to within two per cent or better. As originally plotted on logarithm paper, it was possible to interpolate for intermediate curves with good accuracy. Any intermediate curve should be correct to within five per cent or better.

The curves have a broader utility than is indicated by equation 33 alone. First note in Figure 17 that as the rectangles approach each other (at X of unity they are adjacent) any one curve rises because of mutual effect. Conversely, when separated by as much as $X=9$ the curve is nearly horizontal; nearly all the force then is caused by the eddy currents of each flux acting on itself. F_∞' has been computed and shown on the chart; these are F' values when $X=\infty$. Two additional uses for the curves then can be made.

First, a single isolated rectangle of flux yields a force (dynes)

$$F=\left(\frac{1}{2}\right)WD^2F_\infty' \tag{34}$$

Second, two flux rectangles as in Figure 16, but containing like fluxes, give a force due to an F' as much less than F_∞' as the direct reading from the chart is above F_∞'. Restated, if F' is as read directly, the force is

$$F=WD^2(2F_\infty'-F') \tag{35}$$

Translational: Size and Shape of Disk

The curves are based on a disk with edges remote, in any direction from either rectangle. However, the writer feels safe in saying that if the disk edge is no closer to the rectangle, anywhere, than twice the length of the rectangle's diagonal, the force will be no more than four per cent below the predicted value. But there undoubtedly will be cases in which an even smaller disk must be used.

The M dimensions in Figure 16 can be reduced, even to zero if necessary, and the only effect is to reduce the force. At $M/H=1/2$, the force still might be 70 per cent of predicted force.

Reduction of L below $L/H=1$ will begin to affect appreciably the linearity of damping. How much would depend also on relative displacement. As a guess, if $L/H=1/2$ and displacement is $L/4$, the force for a given velocity might vary as much as three per cent from average.

A-C Flux Damping

The damping of disks moving through an a-c flux is subject to the same analyses and procedures as were presented for nonvarying flux. The average force or torque will be found by using the rms values of flux or density.

Discussion

B. E. Lenehan (Westinghouse Electric Corporation, Newark, N. J.): Problems which are basically magnetic field problems are nearly always more difficult than circuit problems, mainly because they are in three dimensions. Their solution generally becomes possible only if they can be reduced to two dimensions; then the field can be plotted and an approximate solution obtained.

This necessary approximation limits the accuracy and usefulness of such a method. Heretofore, it generally has been considered simpler and more accurate to construct samples to investigate the effects of the various factors, rather than to depend on a lengthy and involved mathematical solution.

The method in this paper uses analogy to a field problem which has been solved and applies the superposition idea to obtain results by a relatively simple method. The time required compares favorably with that of constructing and testing samples. We plan to investigate the method and check its practicability.

Some conclusions in the paper seem to be contrary to experience, but this is evidently the result of assuming constant fluxes in instead of constant flux densities. The latter is a more logical assumption. When two fluxes assumed constant are brought toward the center, the area occupied must decrease with the radius. When constant flux density is assumed, the fluxes decrease in this manner, so the torque factor is multiplied by C^2/A^2. This leads to another possibility of integrating the torque in polar co-ordinates by equation 16. If Figure 6 of the paper is replotted with T_pC^2/A^2 as ordinate, which corresponds to constant flux density, the curve yields a broad maximum around $C/A=0.7$, which agrees with experience. This is shown in Figure 1 of this discussion.

Figure 1

Our procedure in cases of this kind has been to map the flux pattern and estimate the current stream lines set up by the voltage field and compute the torque by electrodynamic formulas against the current flux, essentially the same procedure as used in the cross-field theory of the induction motor. This permits an estimate of the effects of disk reactance, which is of importance on frequencies above 60 cycles.

The procedure outlined by Professor Moore is interesting and should prove to be valuable, particularly when used as a preliminary step to a full investigation using test samples with the several variables involved.

J. A. M. Lyon and **J. F. Calvert** (Northwestern University, Evanston, Ill.): This paper is very stimulating from the point of view of engineering analysis. Professor Moore has had the courage to set aside classical mathematical procedures and to develop his own analysis for eddy currents and torques in circular disks.

One of the impressive points of this paper has been the clarity of the author in making his theory apply for the edge effects of a disk using the method of images. Some of us probably have been prone to think that in order to provide either sufficient driving or damping torque, pole pieces should be located near the periphery of an eddy current disk. The treatment of the boundary conditions by the image method, which

gives rise to an interpretation including negative torques, certainly aids in obtaining a clear physical picture of the dependence of net torque on the positions of the bundles of magnetic flux piercing the disk.

It may be of interest to note in connection with this paper the similarity in form of the following general relations

$$\int H \cdot dl = \int\int i \cdot dS \tag{1}$$

$$\int E \cdot dl = \int\int = \frac{dB}{dt} \cdot dS$$
$$= -\frac{d\phi}{dt}$$
$$= \int \rho i \cdot dl \tag{2}$$

where in rationalized MKS units

H = magnetic field intensity
B = magnetic flux density
S = area
l = length of path
E = electric field intensity
ϕ = magnetic flux
i = current density
ρ = resistivity in the disk

Whereas we normally think of a current in electric machines as linked by the flux, we find here that it is convenient to think of the flux linked by a current. Equation 2 may be used to map a 2-dimensional current field in the disk both outside and inside the changing flux. If this is done (in a manner analogous to that normally employed in mapping 2-dimensional magnetic fields using equation 1) by the use of equation 2, tubes of equal current are drawn everywhere over the disk, and these are intersected by a family of lines at right angles to the directions of the current flow. These would be arranged to result in curvilinear squares outside the pencil of changing flux and curvilinear rectangles on the disk inside the pencil of changing flux. On the disk the I^2R or heat loss is the same in each curvilinear square which lies outside the region of changing flux and is less in each curvilinear rectangle which lies within the region of changing flux by the ratio of length to width of the rectangle. Here length is taken in the direction of the current flow in the disk.

Refer now to the electrical analogue in Professor Moore's paper where the flux pencil has been replaced by a current and where the edge effect of the disk has been replaced by imaged conductors. Instead of imaged conductors a current sheet of appropriate densities might be assumed at the line representing the edge of the disk. For details see reference 1. This procedure is not limited to disk boundaries which permit imaging. Possibly a similar procedure might be used in accordance with equation 2 using a sheet of flux at the line representing the edge of the disk.

The charts which Professor Moore has presented as aids to actual computation of torques are a good example of how he vigorously has pushed his analytical theories to a successful conclusion by actually providing the tools to use for the solution of a variety of problems.

REFERENCE

1. FORCES IN TURBINE GENERATOR STATOR WINDINGS, J. F. Calvert. AIEE TRANSACTIONS, volume 50, 1931, pages 178–94.

William R. Smythe (California Institute of Technology, Pasadena, Calif.): The replacement of a flux band by a pencil pair greatly reduces the labor of calculating the eddy current damping torque on a rotating disk and may be justified as follows:

Consider the narrow flux band of Figure 10 of the paper with width δr across which the ohmic voltage drop is negligible compared with the uniform potential difference $V_+ - V_-$ maintained between its boundaries by the electromotive force, equation 18, generated inside. Outside the boundary where there are no sources nor sinks of current the divergence of the area current density i must be zero and by Ohm's law i equals the product of the area conductivity b/ρ by the negative potential gradient. Writing the relations symbolically gives

$$\nabla \cdot i = -\nabla \cdot (b/\rho) \nabla V$$
$$= -(b/\rho) \nabla^2 V$$
$$= 0 \tag{1}$$

Thus the differential equation and boundary conditions satisfied by V are

$$\nabla^2 V = 0$$
$$V_+ - V_- = \omega r B \, \delta r \times 10^{-8} \tag{2}$$

Now let two infinite parallel wires carrying currents I and $-I$ pierce the current shell normally at opposite ends of the flux band which coincides with a section of the magnetic shell that joins them. The differential equation and boundary conditions satisfied by the scalar magnetic potential Ω of this shell are then

$$\nabla^2 \Omega = 0$$
$$\Omega_+ - \Omega_- = I \tag{3}$$

Evidently the solutions of equations 2 and 3 are mathematically identical provided we identify $\omega r B \delta r \times 10^{-8}$ with I, V with Ω, and i with bH/ρ.

The law of Biot and Savart shows that at any point P the value of $-\nabla \Omega$ or H that satisfies equation 3 is determined by the radius vectors drawn from the two wires to P. Similarly i must be determined by vectors drawn from the ends J and K of the flux band. The component of H resulting from the K-wire is $2I/S_k$ so that of i resulting from K is

$$i_k = \frac{2\omega b r B \delta r}{\rho S_k} \times 10^{-8} \tag{4}$$

and is normal to S_k. Now from equation 5 we may write the current density caused by a flux pencil in the form

$$i_k = \frac{I}{ds} = \frac{b}{\rho S_k} \frac{d\phi_k}{dt} \times 10^{-8} \tag{5}$$

Therefore, the flux band may be replaced by two equal and opposite flux pencils, one at each end, whose strengths are

$$\phi_{k,J} = \pm 2\omega B r \delta r t \tag{6}$$

Theory and Application of Complex Logarithmic and Geometric Mean Distances

THOMAS JAMES HIGGINS
MEMBER AIEE

THE geometric mean distance D_1 between a point and a plane geometric part (a line segment, curve segment, closed curve, or area lying in a plane containing the point) is defined by

$$\log D_1 = (1/S_1) \int_{S_1} \log d \, dS \qquad (1)$$

wherein d is the distance between the given point and an arbitrary point in the second geometric part, and S_1 is the length or area of this part.

The geometric mean distance D_{12} between two coplanar geometric parts S_1 and S_2 is

$$\log D_{12} = (1/S_1S_2) \int_{S_2} \int_{S_1} \log d \, dS_1 \, dS_2 \qquad (2)$$

wherein d is the distance between arbitrary points in the given geometric parts, and S_1 and S_2 are the respective lengths or areas of these parts. If S_1 and S_2 are identical in shape and position, D_{11} is termed the self geometric mean distance of $S_1 \equiv S_2$ to itself. If S_1 and S_2 are nonidentical, D_{12} is termed the mutual geometric mean distance between S_1 and S_2.

The logarithm of a geometric mean distance is termed a logarithmic mean distance. Equations 1 and 2 evidence the general definition of the logarithmic mean distance between two geometric parts as the average value of the summation of the logarithms of the distances between all possible pairs of points comprising the two geometric parts, the two points of a pair being chosen from different geometric parts.

Obviously, knowledge of the logarithmic mean distance furnishes knowledge of the corresponding geometric mean distance and conversely. Accordingly, in developing general theory it is only necessary to speak of one of the two. In textbooks, which maintain the tradition established in Maxwell's text,[1] the geometric mean distance is dealt with. Inasmuch, however, as the logarithmic mean distance rather than the geometric mean distance is utilized in actual practice [for example, the d-c or low-frequency a-c inductance of a transmission line or an industrial bus comprised of two nonmagnetic parallel cylindrical conductors of cross sections S_1 and S_2 is

$$L = 2 \log (D_{12}^2/D_{11}D_{22})$$
$$= 4 \log D_{12} - 2 \log D_{11} - 2 \log D_{22}$$

abhenrys per centimeter of line or bus length] it would seem preferable to work in terms of the logarithmic mean distance, as is done in the remainder of this paper.

As indicated by equations 1 and 2, evaluation of the logarithmic mean distance between two specified geometric parts requires a one- (for a point and a line or curve segment) to four-fold (for two plane areas) integration, of difficulty depending on the shape and relative location of the specified geometric parts. In general, if the given configuration is other than one of the several simple cases which long have been evaluated, the mathematical difficulties associated with integrating equations 1 and 2 are very considerable (see, for example, the analysis encompassed in obtaining the logarithmic mean distance for the not very complicated geometrical arrangement of two arbitrarily located parallel-sided rectangles treated in reference 2).

Recently, however, the writer has evolved a method for determining logarithmic mean distances in which the just mentioned mathematical difficulties are largely obviated. This method hinges on the use of complex variable theory rather than the real variable theory utilized by Maxwell[1,3] (originator of the theory of logarithmic mean distance), Gray,[4] Guye,[5,6] Sumec,[7] Orlich,[8,9,10] Rosa,[11,12,13] Grover,[10,13,14] and all others[17] who to date have calculated logarithmic mean distances. In essence, the method involves expressing the right-hand member of equations 1 or 2 as the real or imaginary part of an integral which is a function of the complex variable $z = x + iy$. This complex integral, unlike the real integrals of equations 1 and 2, is evaluated easily. Moreover, the resulting complex expression, hereafter termed the complex logarithmic distance, yields yet another advantage.

The formulas for the logarithmic mean distances of the geometric configurations encountered in practice comprise algebraic summation of a number of logarithmic, arctangentic, and algebraic terms. Because of the many transcendental terms, numerical computation with these formulas is most laborious. In consequence, it is most desirable to know the equivalent rapidly converging series which is especially suited to computation. The series equivalent of a given formula commonly has been obtained, to date, by replacing each component term by its power series, and summing corresponding powers of the variable. Obtaining the equivalent series of a specified logarithmic mean distance in this fashion requires, however, a considerable amount of labor. Contrari-

Paper 47-2, recommended by the AIEE committee on basic sciences for presentation at the AIEE, winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted July 29, 1946; made available for printing October 11, 1946.

THOMAS JAMES HIGGINS is associate professor of electrical engineering, Illinois Institute of Technology, Chicago, Ill.

wise, the equivalent series of the complex logarithmic mean distance can be derived with little labor, and from this series can be obtained by inspection the real or imaginary part which is the desired series for the logarithmic mean distance.

It appears, therefore, that use of the complex variable rather than the real variable largely eliminates the mathematical difficulties encountered in working out specific formulas for logarithmic mean distances and in obtaining their equivalent series.

Now much of the theory pertinent both to the design and to the calculation of the resulting electrical and mechanical performance of power[18] and communication[19] transmission lines, industrial distribution busses[17,20,21] transformer windings,[22,23] coils and solenoids for induction heating units and various other purposes,[16,23] and of yet other current-carrying apparatus is couched in terms of logarithmic mean distances. In consequence, it is obviously most desirable that the above mentioned advantages stemming from use of complex logarithmic mean distances be generally available.

The requisite theory is developed under the heading "General Theory." Application of this theory and substantiation of the very considerable advantages accruing to use of it are afforded by solution of typical problems given under "Illustrative Examples."

General Theory

Given the real integral

$$G(X,Y) = \int_{S_1} E(X,Y)dS \qquad (3)$$

Figure 1. Relative location of two line segments

let $Z = \Psi(W)$ be a conformal transformation[24] which maps the line or curve segment S_1 of the $Z = X + iY$ plane on a line segment U_1 in the right-hand half of the $W = U + iV$ plane. In virtue of the specified transformation X, Y and $dS = |dZ/dW|dU$ are known functions of U and V. Substituting accordingly in equation 3 yields

$$G[X(U,V),\ Y(U,V)] = \int_{U_1} E[X(U,V),\ Y(U,V)]|dZ/dW|dU \qquad (4)$$

or equivalently

$$H(U,V) = \int_{U_1} F(U,V)dU \qquad (5)$$

whereof

$$H(U,V) = G(X,Y)$$

and

$$F(U,V) = E(X,Y)|dZ/dW|$$

Let $F(U,V) = f_1(U,V)$ be the real part of an analytic function $f(W) = f_1(U,V) + if_2(U,V)$. Consider the complex integral

$$\begin{aligned} h(W) &= \int_{U_1} f(W)dW \\ &= \int_{U_1}(f_1+if_2)\ d(U+iV) \\ &= \int_{U_1}(f_1\ dU - f_2\ dV) + \\ &\qquad i\int_{U_1}(f_2\ dU + f_1\ dV) \end{aligned} \qquad (6)$$

Over the path of integration $U = U_1$ we have $dU = dU$ and $dV = 0$.
Thus

$$\begin{aligned} h(W) &= \int_{U_1} f_1\ dU + i\int_{U_1} f_2\ dU \\ &= \int_{U_1} F(U,V)\ dU + i\int_{U_1} f_2 dU \end{aligned} \qquad (7)$$

The right-hand member of equation 5 is the real part of the right-hand member of equation 7; whence $H(U,V)$ must be the real part of $h(W)$. Similarly, if $F(U,V)$ is taken as the imaginary part of $f(W)$, $H(U,V)$ will be the imaginary part of $h(W)$.

The foregoing analysis is to be epitomized as follows:

Theorem I. Let $Z = \Psi(W)$ be a conformal transformation which maps the linear segment S_1 of the Z plane on the line segment U_1 in the right-hand half of the W plane. If under this transformation the real function $E(X,Y)\ dS$ goes over into the real part or the imaginary part of the complex function $f(W)dW$, the real integral $\int_{S_1} E(X,Y)dS$ is, respectively, the real part or the imaginary part of the complex integral $\int_{U_1} f(W)dW$.

In a precisely similar fashion the following can be established:

Theorem II. Let $Z = \Psi(W)$ be a conformal transformation which maps the linear segment S_1 of the Z plane on the line segment V_1 in the upper half of the W plane. If under this transformation the real function $E(X,Y)dS$ goes over into the real part or the imaginary part of the complex function $f(W)dW$, the real integral $\int_{S_1} E(X,Y)dS$ is, respectively, the imaginary part or the negative of the real part of the complex integral $\int_{V_1} f(W)dW$.

With reference to logarithmic mean distance theory the importance of the analysis indicated in theorems I and II is as follows. Determination of a logarithmic mean distance necessitates evaluation of a multiple integral whereof the successive integrals are of the type of equation 3. Commonly, evaluation in terms of real variables hinges on transforming the integral in question into an integral of the form of equation 5 through appropriate change in the variable of integration. Successful determination of the change to be made depends heavily on the skill and experience of the calculator; further, the transformed integral, though simpler than the original integral, usually is yet difficult to integrate. These difficulties increase with successive integrals. If these obstacles are surmounted, the resulting formula for the logarithmic mean distance is complicated in form, contains numerous transcendental terms, and requires considerable analytic manipulation before the equivalent series, or formulas pertinent to special cases of the general geometric configuration, can be derived from the formula for the general case.

Such analytic difficulties do not ensue when the complex variable approach sketched previously is utilized. The conformal transformation to be used is more

Figure 2. Two identical line segments of length a and 120-degree included angle

or less obvious. Application of this transformation to the given integral in accordance with Theorem I or II automatically effects the desired change of variable; usually, the associated complex integral is so simple that it can be integrated by inspection. Successive integrals are handled as easily. The resulting formula for the complex logarithmic mean distance is simple in form, contains few terms, and is manipulated readily to yield the equivalent series or formulas pertinent to special cases of the given geometrical configuration. Selection of the real or imaginary part yielding the real logarithmic mean distance is a matter of inspection.

In substantiation of these remarks and in illustration of the analytic detail encompassed in use of the complex variable analysis consider the following examples.

Illustrative Examples

Example 1. The problem is to calculate the logarithmic mean distance between two arbitrarily located line segments (Figure 1).

From equation 2 we have

$$\log D_{12} = (1/S_1S_2)\int_{S_2}\int_{S_1}\log\left[(X-x)^2+(Y-y)^2\right]^{1/2}dS_1\,dS_2$$
$$= (1/S_1S_2)\int_{S_2}\int_{S_1}\log|Z_1-z_1|dS_1\,dS_2 \tag{8}$$

wherein (X, Y) are the co-ordinates of an arbitrary point in S_1 and (x, y) those of an arbitrary point in S_2.

The conformal transformation $W = Ze^{-i\theta}$ maps the line segment S_1 on the line segment $|Z_1| \leq U_1 \leq |Z_2|$ of the real axis of the W plane. Under the transformation we obtain

$$\int_{S_1}\log|Z-z|dS_1 = \int_{|Z_1|}^{|Z_2|}\log|We^{i\theta}-z|\times|e^{i\theta}|dU$$
$$= \int_{|Z_1|}^{|Z_2|}\log|We^{i\theta}-z|dU \tag{9}$$

In virtue of the identity, log (complex function) = log (modulus of function) + i (phase of function), the right-hand member of equation 9 can be evaluated by theorem I as follows:

$$\int_{S_1}\log|Z-z|dS_1$$
$$= Re\int_{|Z_1|}^{|Z_2|}\log(We^{i\theta}-z)dW$$
$$= Re\int_{|Z_1|}^{|Z_2|}e^{-i\theta}\log(We^{i\theta}-z)dW\,e^{+i\theta}$$
$$= Re\int_{|Z_1|e^{i\theta}}^{|Z_2|e^{i\theta}}e^{-i\theta}\log(Z-z)dZ$$
$$= Re\int_{Z_1}^{Z_2}e^{-i\theta}\log(Z-z)dZ$$
$$= Re\left\{e^{-i\theta}\left[(Z-z)\log(Z-z)-(Z-z)\right]_{Z_1}^{Z_2}\right\} \tag{10}$$

wherein Re indicates the real part of the complex expression.

The conformal transformation $W = ze^{i\theta}$ maps the line segment S_2 on the line segment $|Z_3| \leq U_2 \leq |Z_4|$ of the real axis of the W plane. Under this transformation we obtain in the fashion

$$\int_{S_2}\left(\int_{S_1}\log|Z-z|dS_1\right)dS_2$$
$$= \int_{S_2}Re\left\{e^{-i\theta}\left[(Z-z)\log(Z-z)-(Z-z)\right]_{Z_1}^{Z_2}\right\}dS_2$$
$$= \int_{|Z_3|}^{|Z_4|}Re\left\{e^{-i\theta}\left[(Z-We^{-i\theta})\times\log(Z-We^{-i\theta})-(Z-We^{-i\theta})\right]_{Z_1}^{Z_2}\right\}\times|e^{-i\theta}|dU$$
$$= Re\int_{Z_3}^{|Z_4|}e^{-i\theta}\left[(Z-We^{-i\theta})\times\log(Z-We^{-i\theta})-(Z-We^{-i\theta})\right]_{Z_1}^{Z_2}dW$$
$$= Re\int_{|Z_3|_e-i\theta}^{|Z_4|_e-i\theta}e^{-i\theta}e^{i\theta}\left[(Z-We^{-i\theta})\times\log(Z-We^{-i\theta})-(Z-We^{-i\theta})\right]_{Z_1}^{Z_2}\times dW\,e^{-i\theta}$$
$$= Re\int_{|Z_3|_e-i\theta}^{|Z_4|_e-i\theta}\left[(Z-We^{-i\theta})\times\log(Z-We^{-i\theta})-(Z-We^{-i\theta})\right]_{Z_1}^{Z_2}\times dW\,e^{-i\theta}$$
$$= Re\int_{Z_3}^{Z_4}\left[(Z-z)\log(Z-z)-(Z-z)\right]_{Z_1}^{Z_2}dz$$
$$= Re\left\{\left(\left[-\frac{1}{2}(Z-z)^2\log(Z-z)+\frac{3}{4}(Z-z)^2\right]_{Z_1}^{Z_2}\right)_{Z_3}^{Z_4}\right\} \tag{11}$$

Substituting from equation 11 in equation 2 yields the desired logarithmic mean distance

$$\log D_{12} = -(1/S_1S_2)Re\left\{\left[\left[\frac{1}{2}(Z-z)^2\times\log(Z-z)-\frac{3}{4}(Z-z)^2\right]_{Z_1}^{Z_2}\right]_{Z_3}^{Z_4}\right\} \tag{12}$$

For the general configuration of Figure 1, $Z_1 = OR\,e^{i\theta}$, $Z_2 = OS\,e^{i\theta}$, $Z_3 = OP\,e^{-i\theta}$ $Z_4 = OQ\,e^{-i\theta}$ and $2\theta = \phi$. Substituting in the right-hand member of equation 12 and effecting the indicated analysis as detailed in Appendix I yields

$$2RS\,PQ\log D_{12} = [2OR\,OP-(OR^2+OP^2)\times\cos\phi]\log RP+[2OS\,OQ-(OS^2+OQ^2)\cos\phi]\log SQ-[2OS\,OP-(OS^2+OP^2)\cos\phi]\log SP-[2OR\,OQ-(OR^2+OQ^2)\cos\phi]\times\log RQ-[OP^2\,\overline{SPR}-OQ^2\,\overline{SQR}+OR^2\,\overline{PRQ}-OS^2\,\overline{PSQ}]\sin\phi-3RS\,PQ \tag{13}$$

wherein, for example, $\overline{SPR}$ indicates the radian measurement of the angle SPR.

Confirmatively, equation 13 is identical with the known formula derived by Maxwell.[1,3] The very considerable simplicity of the derivation given here is appreciated best by comparing it with the analysis involved in direct integration of equation 8 as effected in Maxwell's[1] original derivation.

Example 2. The problem is to derive the geometric mean distance between two identical line segments of length a, relatively located as in Figure 2.

For this particular case of the general configuration of Figure 1, $Z_1 = Z_3 = 0$, $Z_2 = Z_4 = ae^{i\pi/3}$. Substituting in equation 12 and performing the indicated arithmetic as detailed in Appendix II yields

$$\log D_{12} = \log a+\frac{3}{4}\log 3+\frac{\sqrt{3}\pi}{12}-\frac{3}{2} \tag{14}$$

Confirmatively, the same value is yielded by equation 13. But in deriving equation 14 from equation 13 considerable manipulation is required. Thus, inasmuch as $OP = OR = RP = 0$, L'Hospital's Theorem[25] must be utilized to determine the values of the indeterminate term $[2OR\,OP-(OR^2+OP^2)\cos\phi]\log RP$; the limiting values of $\overline{SPR}$ and $\overline{PRQ}$ must be discerned; the proper quadrantal algebraic signs must be assigned to the trigonometric functions—a fact not clear from Maxwell's statement of the formula of equation 13. Contrariwise, obtaining equation 14 from equation 12 requires only routine calculation with complex numbers.

Example 3. The problem is to determine the logarithmic mean distance between two parallel-sided rectangular areas of arbitrary relative location (Figure 3).

From equation 2 we have

$$RSrs\log D_{12} = \int_0^s\int_0^r\int_{P+s}^{P+S+s}\int_{D+r}^{D+R+r}\log\left[(X-x)^2+(Y-y)^2\right]^{1/2}dX\,dY\,dx\,dy \tag{15}$$

Each of the differential elements dX, dY, dx, and dy is parallel to a co-ordinate axis of the given plane. Hence for the variables X, Y taken in turn the required transformation is $Z = W$ and for the variables x, y taken in turn the required transformation is $z = W$. Accordingly $X = x = U$ and $Y = y = V$, indicating that we work directly in the given plane.

Thus, recognizing (as in equation 8) that the integrand is the real part of log $(Z-z)$, that dX is parallel to the real axis of Z, dY to the imaginary axis of Z, dx to the real axis of $z(\equiv Z)$ and dY to the imaginary axis of z we obtain by succes-

Figure 3. Relative location of two parallel-sided rectangles

sive application of theorems I and II

$$RSrs \log D_{11} = \int_0^r \int_0^s \int_{P+s}^{P+S+s} \left[Re \times \int_{(D+r)+iY}^{(D+R+r)+iY} \log (Z-z) dZ \right] dY\, dx\, dy$$

$$= \int_0^r \int_0^s \int_{P+s}^{P+S+s} Re \left\{ [(Z-z) \times \log (Z-z) - (Z-z) \Big]_{(D+r)+iY}^{(D+R+r)+iY} \right\} \times dY\, dx\, dy$$

$$= \int_0^r \int_0^s \int_{P+s}^{P+S+s} \left\{ Re[(Z-z) \times \log (Z-z) - (Z-z) \Big]_{D+r}^{D+R+r} dY\, dx\, dy \right.$$

$$= \int_0^r \int_0^s \left[\left[Im \left\{ \frac{1}{2}(Z-z)^2 \log(Z-z) - \frac{3}{4}(Z-z)^2 \right\} \right]_{D+r}^{D+R+r} \right]_{P+s}^{P+S+s} dx\, dy$$

$$= \int \left[\left[\left[Im \left\{ \frac{1}{6}(Z-z)^3 \log (Z-z) - \frac{11}{36}(Z-z)^3 \right\} \right]_{D+r}^{D+R+r} \right]_{P+s}^{P+S+s} \right]_0^s dy$$

$$= -\frac{1}{24} \left[\left[\left[Re \left\{ (Z-z)^6 \log(Z-z) - \frac{25}{12}(Z-z)^4 \right\} \right]_{D+r}^{D+R+r} \right]_{P+s}^{P+S+s} \right]_0^s \quad (16)$$

Recalling the identity

$$\log (Z-z) = \log [(X-x)^2 + (Y-y)^2]^{1/2} + i \tan^{-1}[(Y-y)/(X-x)] \quad (17)$$

wherein the arc tangent takes on the proper quadrantal value in accordance with use of the principal branch of the logarithmic function $[-\pi < \text{phase } (Z-z) \equiv \tan^{-1} (Y-y)/(X-x) \leq \pi]$, we obtain from equation 16

$$RSrs \log D_{11} = -\frac{25}{12} RSrs - \frac{1}{24} \sum_{i=1}^{4} \sum_{j=1}^{4} (-1)^{i+j} K(A_i, B_j) \quad (18)$$

wherein

$$K(A_i, B_j) = (A_i^6 - 6A_i^4 B_j^2 + B_j^6) \log (A_i^2 + B_j^2)^{1/2} - 6A_i^5 B_j \tan^{-1}(B_j/A_i) + 4A_i B_j^5 \tan^{-1} (B_j/A_i) \quad (19)$$

and

$$A_1 = |D+R+r|;\ A_2 = |D+R|;\ A_3 = |D|;\ A_4 = |D+r| \quad (20)$$

$$B_1 = |P+S+s|;\ B_2 = |P+S|;\ B_3 = |P|;\ B_4 = |P+s| \quad (21)$$

The ease with which equation 18 is obtained is appreciated readily if the present derivation be compared with the original derivation[2] of this formula, effected by direct integration of equation 15.

Example 4. The problem is to determine the series equivalent of the formula for the self geometric mean distance of a rectangular area having sides r and s.

The configuration of this example is a special case of Figure 3; the rectangles are identical and coincident. Hence $R = r$, $S = s$, $D = -r$, $P = -s$, whence equations 20 and 21 yield $A_1 = A_3 = r$, $A_2 = A_4 = 0$, $B_1 = B_3 = s$, and $B_2 = B_4 = 0$. Substituting appropriately in equations 18 and 19 yields

$$\log D_{11} = -\frac{25}{12} - \left(\frac{1}{6} r^2 s^2\right) [(r^4 - 6r^2 s^2 + s^4) \log (r^2+s^2)^{1/2} - 4r^2 s \tan^{-1} s/r + 4rs^2 \tan^{-1} s/r - r^4 \log r - s^4 \log s] \quad (22)$$

In virtue of the relationship of equations 16, 17, and 18 it is obvious that the algebraic sum of the first three terms in the bracketed quantity in the right-hand member of equation 22 is $Re[(r + is) \times \log (r+is)]$. This noted, it is evident that the bracketed quantity can be written in the form, $Re[r^4(1 + t)^4 \log(1 + t)] - 6r^2 s^2 \log r$, wherein t is the complex number (ir/s). Accordingly equation 22 can be written

$$\log D_{11} = -\frac{25}{12} + \log r - \frac{1}{6}(r/s)^2 \times Re[(1+t)^4 \log (1+t)] \quad (23)$$

Now $(1+T) \log(1+T)$, wherein T is a complex variable, can be expanded in a power series about the point $T = 0$. This power series represents the function for all values of T such that $|T| < 1$. At $T = -1$, whereof $|T| = 1$, the function has a singularity—a branch point; whence in general the function is not represented by its power series at points such that $|T| \geq 1$. Applying Taylor's theorem yields

$$(1+T)^4 \log (1+T) = T + \frac{7}{2}T^2 + \frac{13}{3}T^3 + \frac{25}{12}T^4 + \ldots \quad (24)$$

wherein $|T| < 1$.

In our particular case we are interested in the real part of the series corresponding to the special value, $T = t = (ir/s)$. Substituting in equation 24 and selecting the real part yields

$$Re[(1+t)^4 \log (1+t)] = -\frac{7}{2}(r/s)^2 + \frac{25}{12}(r/s)^4 - \ldots \quad (25)$$

valid for $(r/s) < 1$. Substituting from equation 25 into equation 23 yields the desired equivalent series

$$\log D_{11} = \log r - \frac{25}{12} + \frac{7}{12}(r/s)^4 - \frac{25}{72}(r/s)^6 + \ldots \quad (26)$$

This series is identical with the known formula. The ease with which it is derived is appreciated readily by one who proceeds to derive it directly from equation 22 by expanding the component terms in power series and summing corresponding powers of (r/s). Yet equation 22 is the simplest of the formulas for logarithmic mean distances between rectangular areas which are utilized in, say, the design of industrial distribution busses.

Appendix I

From equation 12 we have

$$2RS\,PQ \log D_{12} = Re\{ -[(Z_3 - Z_4)^2 \times \log (Z_3 - Z_4) - 3(Z_3 - Z_4)^2/2] + [(Z_3 - Z_4)^2 \log (Z_3 - Z_4) - 3(Z_3 - Z_4)^2 + 2] + [(Z_1 - Z_4)^2 \log (Z_1 - Z_4) - 3(Z_1 - Z_4)^2/2] - [(Z_1 - Z_4)^2 \times \log (Z_1 - Z_4) - 3(Z_1 - Z_4)^2/2]\} \quad (27)$$

Typically

$$(Z_3 - Z_4) = |Z_3| (\cos \theta + i \sin \theta) - |Z_4| \times (\cos \theta - i \sin \theta) = (|Z_3| - |Z_4|) \cos \theta + i(|Z_3| + |Z_4|) \times \sin \theta \quad (28)$$

whence by recalling simple trigonometric transformations for $2\theta = \phi$ yields

$$(Z_3 - Z_4)^2 = (|Z_3|^2 + |Z_4|^2) \cos \phi - 2|Z_3||Z_4| + i(|Z_3|^2 - |Z_4|^2) \sin \phi = (OS^2 + OQ^2) \cos \phi - 2OS\,OQ + i(OS^2 - OQ^2) \sin \phi \quad (29)$$

Next

$$\log (Z_3 - Z_4) = \log |Z_3 - Z_4| + i \text{ phase } (Z_3 - Z_4) = \log QS + i(\theta + \overline{OSQ}) \quad (30)$$

Accordingly

$$Re\{ -[(Z_3 - Z_4)^2 \log (Z_3 - Z_4) - 3(Z_3 - Z_4)^2/2]\} = [2OS\,OQ - (OS^2 + OQ^2) \cos \phi] \times \log QS + (\theta + \overline{OSQ})(OS^2 - OQ^2) \times \sin \phi - 3[(OS^2 + OQ^2) \cos \phi - 2OS\,OQ]/2 \quad (31)$$

The real parts of the other three terms in the right-hand member of equation 27 can be written down by analogy. Adding these four real parts, cancelling like terms, and transforming the four terms typified by $[OS^3(\overline{OSQ}-\overline{OSP})\sin\phi]$ into the form typified by $[OS^3\,\overline{PSQ}\sin\phi]$ yields equation 13.

Appendix II

From Figure 2 we have $Z_1=Z_2=0$, $Z_3=ae^{i\pi/3}$, $Z_4=\overline{Z}_3=ae^{-i\pi/3}$, $RS=PQ=a$. Substituting in equation 27 yields

$$\begin{aligned}2a^3\log D_{12} &= Re\{-[(Z_3-\overline{Z}_3)^3\log(Z_3-\overline{Z}_3)-\\ &\quad 3(Z_3-\overline{Z}_3)^3/2]+[Z_3^3\log Z_3-\\ &\quad 3Z_3^3/2]+[\overline{Z}_3^3\log(-\overline{Z}_3)-3\overline{Z}_3^3/2]\}\\ &= Re[-(Z_3-\overline{Z}_3)^3\log(Z_3-\overline{Z}_3)+\\ &\quad Z_3^3\log Z_3+\overline{Z}_3^3\log(-\overline{Z}_3)-3Z_3\overline{Z}_3]\end{aligned} \tag{32}$$

Substituting as indicated in equation 32, performing the indicated simple complex arithmetic in which $\log(-\overline{Z}_3)=\log ae^{i2\pi/3}$ inasmuch as we are working on the principal branch $-\pi <$ phase $Z \leq \pi$), and collecting like terms yields equation 14.

Equivalent Circuit of the Primitive Rotating Machine With Asymmetrical Stator and Rotor

GABRIEL KRON
MEMBER AIEE

Synopsis: The equations and equivalent circuits of all standard types of rotating electric machinery operating under arbitrary conditions may be derived as special cases of a single generalized rotating machine, the so-called primitive machine. This paper derives the steady-state equivalent circuit of the primitive machine having unbalanced rotor as well as stator. That is, the load or transmission line connected to a salient-pole synchronous machine is assumed to be unbalanced (due to faults, short circuits, and so forth), or the load connected to the slip rings of an induction motor is assumed to be unbalanced. The single-phase alternator, instrument Selsyns, and also sudden short-circuit studies are cases that require an infinite series of time harmonics in the stator and rotor windings in addition to the fundamental. It is assumed that these time harmonics are due to space waves with fundamental pairs of poles rotating at different speeds. The effect of the harmonic space waves is not considered. A paper by A. W. Rankin[1] shows network analyzer studies made of the harmonic currents and torques of a single-phase alternator.

The Balanced Primitive Machine

THE equivalent circuit of the primitive machine in which either the stator or the rotor is balanced has been given in reference 2 and is reproduced in Figure 1. There are two stator and two rotor windings assumed with one member having salient poles. As was shown, the inductances represent the underlying magnetic circuit in which the fluxes flow, and the position of the resistance represents the arrangement of the coils on the magnetic circuit.

While the reactances are calculated at unit frequency, the fundamental frequency of currents along the stationary reference axes is assumed to be f, a fraction of unity. The numbers $f + v$, and so forth, by which the resistances and impressed voltages are divided, show the actual frequencies of the currents in the particular coils. In commutator machines where the ratio of the generated to induced voltages due to a flux line is not unity but k, the rotor speed v should be replaced by kv. The resultant flux linking each coil is the voltage E while the torque due to the coil is the power E^*i.

The Unbalanced Primitive Machine

When both the stator and rotor winding are unbalanced (still assuming saliency on one member only), in the stator (or field) flow not only a current of frequency f, but also even harmonics of the rotor speed v, namely $f \pm 2v$, $f \pm 4v$, and so forth. In the rotor (or armature) flow in addition to f odd harmonics of v, namely $f \pm v$, $f \pm 3v$, $f \pm 5v$, and so forth.

For each frequency of stator and rotor currents there exists in the equivalent circuit a set of forward and backward meshes (Figure 2) that are coupled together by the unbalanced rotor (armature) impedances. The stator and rotor circuits are staggered and are coupled together through the air gap reactances. Again the numbers by which the resistances and impressed voltages are divided show the actual frequency of currents in the coil, such as $f - 2v$ or $f + 3v$. While the two stator reference axes are denoted by d and q, the two rotor reference axes, along which the resistances and reactances are known, are denoted by a and b. For an induction motor a and b are the slip-ring axes, while for a synchronous machine they are the armature axes.

Figure 1. Two different forms of the equivalent circuit of the primitive rotating machine

Paper 47-3, recommended by the AIEE committee on electric machinery for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted May 31, 1946; made available for printing October 22, 1946.

GABRIEL KRON is a consulting engineer, General Electric Company, Schenectady, N. Y.

Table I. Calculation of Torques

Constant Torques

$E_{-y}{}^*i^{f-y}=W_1+jQ_1$	$E_{b-z}{}^*i^{b-z}=W_4+jQ_4$
$E_{xf}{}^*i^{fx}=W_2+jQ_2$	$E_{bz}{}^*i^{\ z}=W_5+jC_5$
$E_{yf}{}^*i^{fy}=W_3+jC_3$	$E_{bz}{}^*i^{zb}=W_6+jC_6$
	$T=W_1+\ldots W_6$

Second Harmonic Torques

$E_{-y}{}^*i^{2f}=W_1+jQ_1$	$E_{-2z}{}^*i^{2z}=W_4+jQ_4$
$E_{xf}{}^*i^{2f}=W_2+jQ_2$	$E_{zb}{}^*i^{2z}=W_5+jQ_5$
$E_{yf}{}^*i^{2f}=W_3+jQ_3$	$E_{2b}{}^*i^{2b}=W_6+jQ_6$
$E_{-y}{}^*i^{-4f}=W_7+jQ_7$	$E_{-2b}{}^*i^{-4b}=W_{10}+jQ_{10}$
$E_{xf}{}^*i^{-4f}=W_8+jQ_8$	$E_{zb}{}^*i^{-2b}=W_{11}+jC_{11}$
$E_{yf}{}^*i^{2f}=W_9+jC_9$	$E_{2b}{}^*i^{2b}=W_{12}+jQ_{12}$
$T=\sqrt{(W_1+\ldots W_{12})^2+[(Q_1+\ldots Q_6)-(Q_7+\ldots Q_{12})]^2}$	

Analogous formulas apply to higher harmonic torques.

The Frequency of Torques

The torques still are measured as cross products of E^*i. The frequency of the latter is determined easily simply by matching the frequencies of E and i as manifested by the resistances in the respective coils. For instance, the actual frequency of E_{xf} is $f+v$ and of i^{-2f} is $f-3v$. Hence, the frequency of the torque due to them is $T=E^*i=-f-v+f-3v=-4v$. Table I gives the torques of various frequencies.

Special Cases

The various types of machines, synchronous and induction, differ from the primitive machine by having certain meshes open. For commutator machines the meshes are not only open but are interconnected in the same manner as the actual machine windings are. When certain windings in a machine are short-circuited permanently the analogous meshes in the equivalent circuit may be removed, but all open-circuit reactances must be replaced by short-circuit (transient and subtransient) reactances.

Figures 3 and 4 give the equivalent circuits of the unbalanced slip-ring induction motor and the single-phase alternator. It should be noted that in the single-phase alternator the mutual couplings between the various harmonics depend on the asymmetry of the direct and quadrature axes.

The Primitive Machine With Rotating Axes

Let the second primitive machine (say a slip-ring induction motor) be given in which the axes are connected rigidly to the stator and rotor. Let also the rotor be loaded unequally, ($r_{ra}\neq r_{rb}$, and so forth), but still smooth magnetically. Because the equation of voltage is

$$e=R\cdot i+p(L\cdot i) \tag{1}$$

the transient impedance tensor is $Z=R+pL$

$$Z=\begin{array}{c|c|c|c|c|}
 & d_s & q_s & a & b \\
\hline
d_s & r_{ds}+L_{ds}p & & M_dp\cos\theta & -M_dp\sin\theta \\
\hline
q_s & & r_{qs}+L_{qs}p & M_qp\sin\theta & M_qp\cos\theta \\
\hline
a & M_dp\cos\theta & M_qp\sin\theta & r_a+L_{Sa}p+L_Dp\cos 2\theta & -L_Dp\sin 2\theta \\
\hline
b & -M_dp\cos\theta & M_qp\cos\theta & -L_Dp\sin 2\theta & r_b+L_{Sb}p-L_Dp\cos 2\theta \\
\hline
\end{array} \tag{2}$$

$$\left.\begin{aligned}
L_D&=\frac{M_d-M_q}{2}\\
L_S&=\frac{M_d+M_q}{2}\\
L_{Sa}&=l_{ra}+\frac{M_d+M_q}{2}\\
L_{Sb}&=l_{rb}+\frac{M_d+M}{2}
\end{aligned}\right\} \tag{3}$$

where l_{ra} and l_{rb} represent the leakage inductances of the rotor and any inductive load.

For an alternator θ is replaced by $-\theta$.

The equation of torque is

$$f=\frac{1}{2}i\cdot\frac{\partial L}{\partial\theta}\cdot i \tag{4}$$

The Frequencies of Currents

If a current with frequency f is assumed to flow in the stator, then (if $\theta=v\omega t$)

1. The term d_sa shows that an $f\pm v$ frequency voltage is induced in the rotor.
2. Assuming an $f\pm v$ current in the rotor, the term ad_s shows that the latter induces an $f\pm 2v$ voltage in the stator.
3. The current due to the latter in turn induces an $f\pm 3v$ frequency voltage in the rotor and so on.

The term aa shows that any rotor current induces in the rotor itself voltages of the same frequency or larger (smaller) by $2v$. Similarly, the term d_sd_s shows that a stator current induces in the stator only voltages of the same frequency.

Summarizing the frequencies of the currents,

1. In the stator flow $f, f\pm 2v, f\pm 4v, f\pm 6v\ldots$ (even harmonics of v)
2. In the rotor flow $f\pm v,\ f\pm 3v,\ f\pm 5v$ (odd harmonics of v)

Time Harmonics

The question now arises, how these various frequencies of voltages may arise. Let sinusoidal windings be assumed on stator and rotor, that is, windings in which only a flux with the fundamental number of pairs of poles can induce a voltage. (This assumption neglects space harmonics, hence excludes squirrel cages.) In that case, higher time harmonics may be induced only by fluxes that rotate faster than the impressed flux. In particular, these fluxes must rotate faster by $\pm 2v$, $\pm 4v$, $\pm 6v$, and so forth as the fundamental flux when viewed from the stator (or faster by $\pm v$, $\pm 3v$, $\pm 5v$, when viewed from the rotor).

Hence, if an infinite set of reference frames is introduced rotating by $\pm 2v$, $\pm 4v$, $\pm 6v$, with respect to a set of reference frames stationary on both stator and rotor, then along these rotating reference frames the time harmonics under consideration must appear as fundamental frequency quantities.

The fact will be ignored that each rotating flux induces not only a voltage that rotates with the same speed as the flux but also other voltages rotating at other speeds. That is, harmonic terms (sine and cosine expressions) in the Z tensor of all reference frames will be neglected and only the constant term kept. This assumption is equivalent to ignoring the second order effects due to the time harmonics. (The time harmonic itself is a second order effect of the fundamental.)

In other words, each of the above reference frames originates another infinite set of reference frames rotating with $\pm 2v$, $\pm 4v$ . . . with respect to itself. Each of the latter in turn starts still an additional infinite set of frames. As a consequence along each frame rotating

with $=2\theta$, $=4\theta$, and so forth, not one current exists, but an infinite set of currents. All of these, but one, will be neglected.

The Primitive Machine With Stationary Axes

As a starting point it is possible to use the rotating axes a, b, or the stationary axes d and q, or the spin axes f, b of the equivalent circuits (that is, symmetrical components on d and q.) In the following the case of stationary axes d and q only will be considered.

Along the d and q axes, using

$$C = \begin{array}{c|cccc} & d_s & q_s & d_r & q_r \\ \hline d_s & 1 & & & \\ q_s & & 1 & & \\ d_r & & & \cos\theta & \sin\theta \\ q_r & & & -\sin\theta & \cos\theta \end{array} \qquad (5)$$

Z becomes (if p also refers to L)

$$Z' = C_t \cdot Z \cdot C + C_t \cdot L \cdot pC + C_t \cdot pL \cdot C \qquad (6)$$

When $r_a = r_b$ and $L_{sa} = L_{sb}$, then these matrices reduce to the usual form since

$$L_{sa} + L_D = L_{rd}$$
$$L_{sa} - L_D = L_{rq}$$

The Equations of Voltage and Torque

In terms of G' and L' the equation of voltage is now

$$e' = R' \cdot i' + L' \cdot pi' + (pL') \cdot i' + G' p\theta \cdot i'$$

But, since $pL' = \dfrac{\partial L'}{\partial \theta}\dfrac{d\theta}{dt} = \dfrac{\partial L'}{\partial \theta} p\theta$, the equation of voltage is

$$e' = R' \cdot i' + L' \cdot pi' + \frac{\partial L'}{\partial \theta} p\theta \cdot i' + G' p\theta \cdot i' \qquad (10)$$

The equation of torque is

$$f' = i' \cdot G' \cdot i' + \frac{1}{2} i' \cdot \frac{\partial L'}{\partial \theta} \cdot i' \qquad (11)$$

(See page 211, equation 27.17, and page 212, equation 27.21 of reference 3 where $\partial L'/\partial\theta$ was assumed to be zero)

The extra terms represent the Christoffel symbol

$$[\alpha\beta, \gamma] = \frac{\partial L_{\beta\gamma}}{\partial x^\alpha} - \frac{1}{2}\frac{\partial L_{\alpha\beta}}{\partial x^\gamma}$$

so that

$$[\alpha\beta, \gamma] i^\alpha i^\beta = \left(\frac{\partial L_{\beta\gamma}}{\partial x^\alpha} - \frac{1}{2}\frac{\partial L_{\alpha\beta}}{\partial x^\gamma}\right) i^\alpha i^\beta \qquad (12)$$

the first term giving the extra harmonic generated-voltages $\dfrac{\partial L'}{\partial \theta} p\theta \cdot i'$ and the second term the extra harmonic torque $1/2 i' \cdot \dfrac{\partial L'}{\partial \theta} \cdot i'$. The equation of motion of a machine with unbalanced rotor and stator is then (if $S_{\alpha\beta\gamma}$ is the torsion tensor)

$$e_\alpha = R_{\alpha\beta} i^\beta + L_{\alpha\beta} p i^\beta + [\beta\gamma, \alpha] i^\beta i^\gamma + 2S_{\beta\alpha\gamma} i^\beta i^\gamma \qquad (13)$$

The interesting fact follows that the effect of the asymmetry in both members is to introduce the Christoffel symbol in the dynamical equation of motion, even though the reference axes are all stationary.

$$\begin{array}{c|cccc} & d_s & q_s & d_r & q_r \\ \hline d_s & L_{ss}p & & M_d p & \\ q_s & & r_{ss} + L_{ss}p & & M_q p \\ d_r & M_d p & M_d p\theta & \begin{array}{c} \dfrac{r_a + r_b}{2} + \dfrac{r_a - r_b}{2}\cos 2\theta \\ + \left[\left(\dfrac{L_{sa} + L_{sb}}{2}\right) + L_D + \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\cos 2\theta\right] p \\ - \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\sin 2\theta\, p\theta \end{array} & \begin{array}{c} \dfrac{(r_a - r_b)}{2}\sin 2\theta \\ + \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\sin 2\theta p - \\ - \left[L_D - \left(\dfrac{L_{sa} + L_{sb}}{2}\right) - \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\cos 2\theta\right] p\theta \end{array} \\ q_r & -M_d p\theta & M_q p & \begin{array}{c} \left(\dfrac{r_a - r_b}{2}\right)\sin 2\theta \\ + \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\sin 2\theta\, p \\ - \left[L_D + \left(\dfrac{L_{sa} + L_{sb}}{2}\right) - \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\cos 2\theta\right] p\theta \end{array} & \begin{array}{c} \dfrac{r_a + r_b}{2} - \dfrac{r_a - r_b}{2}\cos 2\theta \\ + \left[\left(\dfrac{L_{sa} + L_{sb}}{2}\right) - L_D - \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\cos 2\theta\right] p \\ + \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\sin 2\theta\, p\theta \end{array} \end{array} \qquad (7)$$

where p now does not refer to L'.

It should be noted that because of the unbalanced rotor now R', L', and G' are all functions of θ. Also

$$G' = C_t \cdot G \cdot C \qquad (8)$$

$$G' = \begin{array}{c|cccc} & d_s & q_s & d_r & q_r \\ \hline d_s & & & & \\ q_s & & & & \\ d_r & & M_q & \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\sin 2\theta & \left(\dfrac{L_{sa} + L_{sb}}{2}\right) - L_D - \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\cos 2\theta \\ q_r & -M_q & & -\left(\dfrac{L_{sa} + L_{sb}}{2}\right) - L_D - \left(\dfrac{L_{sa} - L_{sb}}{2}\right)\cos 2\theta & -\left(\dfrac{L_{sa} - L_{sb}}{2}\right)\sin 2\theta \end{array} \qquad (9)$$

Figure 2. The primitive machine with unbalanced stator and rotor. (For a synchronous machine v and i (or E) have opposite sign)

The Successive Steps of Transformations

Let the following four sets of reference frames be introduced, each frame consisting of two perpendicular stator and two perpendicular rotor axes,

1. A stationary frame. This is the standard frame.
2. A frame rotating with an instantaneous velocity $2p\theta = 2v$ clockwise (in the same direction as the rotor v).
3. A frame rotating with $2p\theta$ counterclockwise.
4. A frame rotating with $4v$ clockwise. Only the rotor frame will be considered.

There are also additional frames rotating with $-4v$, $\pm 6v$, and so forth, but they are not considered in the analysis, only in the equivalent circuit. Their effect follows automatically from those of the $\pm 2v$ and $\pm 4v$ frames.

Three successive transformations will be performed.

1. Starting with the stationary d_r, q_r rotor axes, the corresponding C is given in (14).

$$C = \begin{array}{c|cccccccccccccc|}
 & d_{s0} & q_{s0} & d_{r0} & q_{r0} & d_{r1} & q_{r1} & d_{s1} & q_{s1} & d_{s-1} & q_{s-1} & d_{r-1} & q_{r-1} & d_{r4} & q_{r4} \\
\hline
d_s & 1 & & & & & & \cos 2\theta & -\sin 2\theta & \cos 2\theta & \sin 2\theta & & & & \\
q_s & & 1 & & & & & \sin 2\theta & \cos 2\theta & -\sin 2\theta & \cos 2\theta & & & & \\
d_r & & & 1 & & \cos 2\theta & -\sin 2\theta & & & & & \cos 2\theta & \sin 2\theta & \cos 4\theta & -\sin 4\theta \\
q_r & & & & 1 & \sin 2\theta & \cos 2\theta & & & & & -\sin 2\theta & \cos 2\theta & \sin 4\theta & \cos 4\theta \\
\hline
\end{array} \tag{14}$$

$$C = \begin{array}{c|cccccccccc|}
 & o_s & o_r & 2_r & 2_s & -2_s & -2_r & 4_r & 4_s & -4_s & -4_r \\
\hline
s & 1 & & & C_2 & C_{-2} & & & C_4 & C_{-4} & \\
r & & 1 & C_2 & & & C_{-2} & C_4 & & & C_{-4} \\
\hline
\end{array} \qquad C = \begin{array}{c|cc|}
 & & \\
\hline
s & C_{2n} & \\
r & & C_{2n} \\
\hline
\end{array}$$

Figure 3. Slip-ring induction motor with unbalanced load

Figure 4. Single-phase alternator

where $n = \pm$ integer

2. Symmetrical components are introduced by

$$C_s = \frac{1}{\sqrt{2}}\begin{array}{c|cc} & f_{-n} & b_{-n} \\ \hline d_{-n} & 1 & 1 \\ q_{-n} & -j & j \end{array}$$

$$C_s' = \frac{1}{\sqrt{2}}\begin{array}{c|cc} & b_n & f_n \\ \hline d_n & 1 & 1 \\ q_n & j & -j \end{array} \qquad (15)$$

It must be remembered that along the backward rotating frames (including the stationary frame) the order in C_s is f, b, while along the forward rotating frames the order in C_s is b, f (C_s' will be denoted then by C_s). Hence

$$C' = \begin{array}{c|ccccccc} & 0_s & 0_r & 2_r & 2_s & -2_s & -2_r & 4_r \\ \hline 0_s & C_s & & & & & & \\ 0_r & & C_s & & & & & \\ 2_r & & & C_s' & & & & \\ 2_s & & & & C_s' & & & \\ -2_s & & & & & C_s & & \\ -2_r & & & & & & C_s & \\ 4_r & & & & & & & C_s' \end{array} \qquad (16)$$

3. p is replaced by $jf\omega$, Z' replaced by $n^{-1}\cdot Z'$, and e by $n^{-1}\cdot e$ where n is the "frequency tensor" whose diagonal terms are given by the array

f_{s0}	b_{s0}	f_{r0}	b_{r0}	f_{r2}	b_{r2}	f_{s2}	b_{s2}	f_{s-2}	b_{s-2}	f_{r-2}	b_{r-2}	f_{r4}	b_{r4}
f	f	$f-v$	$f+v$	$f-v$	$f+v$	$f-2v$	$f+2v$	$f-2v$	$f+2v$	$f-3v$	$f+3v$	$f-3v$	$f+3v$

Discussion

A. W. Rankin (General Electric Company, Schenectady, N. Y.): Quantitative data on synchronous machine operating characteristics as calculated from the equivalent circuits developed by Gabriel Kron are given in a related paper by this discusser.[1] This paper contains calculated data illustrating the torque–slip and current–slip curves of a synchronous machine during asynchronous operation, and calculated data of the damper-bar currents during both asynchronous and single-phase operation. The calculated data of single-phase operation were obtained from the equivalent circuits developed by Kron in the paper now under discussion, and the calculated data of asynchronous operation were obtained from equivalent circuits developed by Kron in a previous article.[2]

Parts *C* and *D* of this paper[1] present calculated data of single-phase operation for both purely reactive and purely resistive loading. This study is of value as it shows the magnitude of the currents in the leading and trailing damper bars, and in addition gives quantitative information on the harmonic torques.

Parts *A* and *B* of the paper[1] are devoted to the study of constant-speed asynchronous operation. Quantitative data are given of the torque–slip characteristics and of the current distribution in the leading and trailing bars of the damper windings.

This reference to the paper[1] is made at this point in order to indicate the location of the quantitative data which complement the circuit developments in the paper by Kron.

Theoretical Approach to Speed and Tie Line Control

ROBERT BRANDT
ASSOCIATE AIEE

Synopsis: Frequency error is an indicator of the amount of excess or deficiency of generation on a whole interconnection, and a frequency–generation line may be established for the whole or for any section which is separated from all others by tie lines over which control may be desired. Automatic equipment is available using these fundamentals under the name of load biased frequency control, which will make the required adjustments to generation to restore normal speed and tie line loadings with a minimum of false moves and by means of which each section will handle, in normal operation, only its own load changes, regardless of the speed of response of its prime movers to correcting impulses. Methods of automatic control by the selective frequency blocking system and the master flat frequency station method are examined and found wanting. The use of uncontrolled speed-sensitive governors with small droop is shown to be disadvantageous if operated in parallel with automatic bias equipment. Consideration is given to practical matters of operation, including an improvement in handling manual generation shifts, action of controller in time of trouble, effect of errors in determining the frequency–generation line, and desirable characteristics of governors.

Characteristics of a Single System

ON any isolated 60-cycle system a speed of just 60 cycles represents an exact balance between the amount of generation and the amount of load. Any speed other than 60 cycles indicates either an excess or a deficiency of generation. There is a definite relation between speed and generation which may be plotted, as shown in Figure 1, as a straight line of a certain slope. (Investigations at various locations indicate a complex relation between load, frequency, and voltage. This discussion uses frequency as the tangible variable to be measured, avoiding the question of whether the underlying cause of the variation is more or less caused by speed alone or associated changes in voltage.) The actual amount of this slope depends on the characteristics of the system load. Perhaps it is not exactly a straight line, but a straight line seems to represent it fairly well in the range which concerns us. In words, slope is an expression of the number of kilowatts to be added to or subtracted from the generation to change the frequency by a definite amount. It follows that as the total load gets larger, the number of kilowatts required to change the frequency by a set amount also must grow, assuming that the load characteristics remain about the same. Thus, also, from day to night, when the load levels vary as much as three to one or even more, the slope of the speed–generation line must change. To calculate the slope of this line from theoretical consideration is difficult, if not impossible, because it would require a detailed analysis of the characteristics of each item of connected apparatus on the system, both customer's and power company's. A more practical approach is the experimental one. That is, find out how many kilowatts must be added to affect the speed, say 1/20 cycle. The result obtained by a test of this sort will not be the theoretical slope, but will be a more useful figure because it reflects exact operating characteristics, not merely of the customers' loads, but also all of the prime movers whose governors have not been definitely blocked. If a deliberate effort is made at a given plant to raise the system speed, some governors, being on the edge of their dead bands, will come into action to oppose the change and thus the apparent slope, if measurement is being made at one location, will be larger in terms of kilowatts per unit speed change than the theoretical slope. Incidentally, this characteristic suggests that the true operating slope of any system is not a straight line, but one which curves in the general manner of the dotted line of Figure 1. That is, if the effort is made to move the speed further from 60 cycles more governors will reach the edge of their dead bands to oppose the change, and, in theory, it should become impossible (with limited kilowatts at the regulating plant) to raise the speed beyond some point not very far from 60 cycles because the manual change at the measuring plant will be nullified completely by unblocked governors at other locations. To relate this condition to practice, we must remember that on most systems it is quite possible for the speed to ride as much as one-tenth cycle above or below standard for minutes on end, even though 90 per cent of the capacity on the system is under the control of governors, theoretically set to maintain 60 cycles. In the discussion following we refer to the resultant slope produced by loads plus random governor effects, and assume it to be a straight line.

Two Systems With Tie Line Between

Consider now the situation when two previously isolated systems are connected by a single or by a group of tie lines. First, the two systems may be considered over-all as one, and for the pair all the foregoing statements still hold. There is a definite over-all slope for the generation–frequency line and any deviation from 60 cycles becomes a measure of either the excess or deficiency of genera-

Paper 47-4, recommended by the AIEE committee on power generation for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted January 28, 1946; made available for printing October 23, 1946.

ROBERT BRANDT is with the New England Power Company, Boston, Mass.

tion. We cannot tell how much of the error is lodged on either side of the tie line. It is possible, however, by considering at the same time both the speed and the amount by which the tie line is over or under schedule to identify at once not only the system responsible for the error, but also the magnitude of that error. This may be explained by a consideration of Figures 2 and 3. Figure 2 represents the purchasing system. Essentially the diagram is the same as that which would be drawn for the system if it were isolated, except that the kilowatt scale reads in terms of deviation from schedule rather than kilowatt error in generation. That this diagram may be drawn properly in this manner follows from the thought that with a system isolated and generating say 10,000 kw more than would be required for 60 cycles, its frequency would rise a known amount, say for instance 1/20 cycle. Suppose the tie line were feeding into the system 10,000 kw above the desired schedule. This excess on the tie acts the same as though generation in one of the local plants were raised by a similar amount, and the effect on the frequency is the same. Figure 3, which represents the selling company, is exactly the same except that the slope of the line has been reversed. This is done merely for convenience and has no particular significance. It could be drawn the other way with appropriate changes in the captions and quadrants. Note that for each system, the slope to be drawn represents the proper slope of that system when isolated. The number of interconnections has no bearing on it. If it were desired to draw for the whole interconnection a single diagram of the type of Figure 1, then the over-all slope line as shown in Figure 4 would be the sum of the individual slopes of all systems involved. To take a concrete example, assume that the selling company has a load of 1,000,000 kw and a generation–frequency slope of 30,000 kw per one-tenth cycle. Assume that the buying company is smaller with a load of 500,000 kw and a slope of 10,000 kw per one-tenth cycle. These, incidentally, are the slopes plotted in Figures 2 and 3. (These examples are illustrative only. The kilowatts per unit speed change, in relation to the total load, is probably larger than the actual figure for most systems.) Figure 4 for the pair of systems must have a slope of 40,000 kw per one-tenth cycle. The justice of this reasoning easily is seen. Suppose the systems were of equal size and with similar load characteristics. When tied together it would require twice as many kilowatts to change both of them by a tenth of a cycle as it would to change either one by the same amount. However, suppose one of the systems was very small compared to the other, with a slope say of 1,000 kw per one-tenth cycle, while the larger system remained the same as our example in Figure 3. The large system then completely overshadows the small one and only 31,000 kw would be needed to change the speed on the combination by one-tenth cycle.

Suppose now that on the 1,000,000 kw–500,000 kw interconnection there appears a speed error of plus 1/20 cycle. It follows from Figure 4 that somewhere at a location as yet unknown there is excess generation of 20,000 kw. Suppose further that the buying company finds itself with 5,000 kw "above schedule coming in" and the selling company, therefore, with a similar amount "over schedule out." This is the condition of point 1 on Figures 2 and 3. It is possible now to locate the generation error entirely on the selling system, since the purchasing company is exactly on its own speed–generation line. Both the tie line and the speed will be restored to normal without any effort on the buying company's part, if the seller will reduce his generation by 20,000 kw. Suppose a second case marked as point 2 on Figures 2 and 3. The speed is 1/20 cycle high, but the tie line is exactly on schedule. In this case each system is responsible for as much of the error as is necessary to change its own speed if isolated by just 1/20 cycle. For the small system this is 5,000 kw, and for the large system 15,000 kw; they add to give the 20,000-kw error of Figure 4.

Consider now one more situation marked as point 3. The speed error is unchanged from the two previous cases, but the tie is now 10,000 kw over schedule toward the purchasing company. Obviously the selling company should reduce its generation. Just as truly, but not so obviously without an examination of Figure 2, the buying company should increase its generation in spite of the high frequency. The decrease should be 25,000 kw, the increase should be 5,000 kw, and the net change will be just the amount required to restore the interconnection speed as well as schedule to normal. Here we see the usefulness of the lines which have been drawn parallel to the main slope line in Figures 2 and 3, and marked drop or raise so many thousand kilowatts. It is thus possible for either system, by noting merely the speed error and the tie line error, to determine at once how many kilowatts and in what direction it should change generation on its own system so that it may be doing its share in restoring the combination to normal and accomplishing the desired result of handling its own load swings on its own plants.

It might appear that satisfactory control, following the foregoing principles, could be accomplished without automatic equipment by having a dispatcher with a tie line telemeter, a frequency indicator, and a chart (similar to those shown in Figures 2 or 3) analyze the situation and order appropriate generation adjustments. Such is not the case

Figure 1

Figure 2. Conditions on the buying company's system

Figure 3. Conditions on the selling company's system (simultaneously with Figure 2)

Figure 4. Conditions on the combined interconnection of Figures 2 and 3

The time consumed and the undivided attention required both eliminate definitely any such "manual" approach. The ordinary biased automatic tie line load controller accomplishes exactly the desired result in theory, at least, and approximates it in practice if the bias has been selected properly and all the rest of the control mechanism responds properly. At this point it may be well to repeat the statement previously made by others that the term "bias" as currently used is somewhat misleading and represents nothing other than a measure of the amount of generation change required for a given speed change on a particular system, if isolated. In other words, it is nothing but our generation–frequency line.

It appears that the systems shown in Figures 2 and 3 with their interconnecting tie line and control equipment, operating along the slope lines as indicated, should be able to control both the speed and the scheduled interchange without any station anywhere on the interconnection acting as a master frequency control station. Not only is this true, but the addition of a master frequency control station would be definitely to the disadvantage of smooth operation. Such a station, which is responsive only to speed, will do the wrong thing and upset conditions rather than help them whenever the combination of conditions of schedule and frequency error lie in the cross-hatched segments shown in Figures 2 and 3. It will be remembered that when we analyzed the conditions at point 3, we found that on the buying company shown in Figure 2 it was necessary to increase the generation even though the speed was high. No master frequency control equipment, which does not have tie line indication biased into it, could make such a move. Yet, any reduction of generation would be wrong and would require extra moves for the ultimate correction of both speed and tie. We may from this reasoning say definitely that a master speed control station is a liability rather than an asset when operated in parallel with biased automatic tie line equipment.

From the same reasoning, it follows that what operating men for many years have spoken of as the free help that comes from uncontrolled governors is not in all cases a help. That is, those governors which happen to be on the edge of their dead bands and which therefore are prodded into activity by a very slight change in speed will be a help only when the tie and frequency errors do not produce a point in the cross-hatched segments. The unintentional error caused by this situation is less on big systems and more on small systems, because on a small system the slope of the speed–generation line is more nearly vertical and thus the cross-hatched segment is larger. When it comes to making a decision as to whether it is more advantageous to do nothing than to do something that is wrong a fraction of the time, it seems as though the "do nothing" theory would be just about as satisfactory. This brings us to the conclusion that all governors which are not to receive their instructions from master equipment which is sensitive to both speed and tie line schedule error had better be rendered insensitive to small changes either by operating hard up against a load limit stop or preferably by a fairly steep droop characteristic. It is suggested that such a droop might well be of the order of five per cent. On such a governor, if the dead band could be narrowed down to the vanishing point, a speed error of one-tenth of a cycle on a 100,000-kw unit would result in a change of generation of 3,300 kw. There would seem to be no particular harm in having the droop as much as ten per cent, in which case the contribution for the same frequency error would be halved. A supersensitive governor with characteristics approaching the isochronous should not be allowed at large on any combination of systems using tie line bias unless it is under control of the bias mechanism.

Selective Frequency or Blocking

Selective frequency, under which method the controller at one end of a tie always is blocked and at the other end active, is illustrated in Figure 5. It represents an attempt to identify the source of error by mechanical means, much as an operator would by noting the directions of speed and tie errors, and to force the correction to originate from the proper end. The feature of this type of control is that it is qualitative only and takes no account of amount; thus the units under its control are inactive whenever there is, for instance, a combination of high frequency and "over schedule in." The implication is that whenever this situation occurs, the trouble lies on the far side of the tie line and the other party should make all the correction. Such a situation is the truth only when the operating point lies on the speed–generation line. To expand this line to fill a whole quadrant is oversimplification. Thus selective frequency operation is at best a partial answer. It avoids the errors which an uncontrolled governor would make with conditions inside the cross-hatched segment, but it fails to make the moves which are required from a consideration of the situation illustrated in Figures 2 and 3.

Complex Interconnections

All of the foregoing principles derived apply equally well to complex interconnections where several systems are involved with many tie lines. It becomes necessary in such a case to control with reference to the algebraic sum of all interconnection schedules, rather than just one. The bias characteristic of the controller should remain as before with the same slope as the system itself would have, if isolated.

Cascade Settings

There is another type of control operation which has seen some use and should be considered. It is called for simplicity

"cascade setting." Tie line bias is used, but instead of allowing each system to set for its own natural slope the intermediate systems of a sprawling interconnected string are set for the sum of the slopes of all systems on one side or the other. Measurement of the ties is confined to one direction only instead of measuring all ties and operating on the net. This feature provides about the only advantage of the method because the multiple metering required on a large system with many connections becomes complicated and expensive. To illustrate, assume a simple case of three systems in a row—*A*, *B*, and *C*—with ties in each direction from *B*. The natural slopes are respectively 20,000, 15,000, and 5,000 kw per one-tenth cycle. Assume initially a balanced conditions with loads on each system of 100,000 kw generation equal to the load, and zero schedule on each tie.

Under the cascade system the controller at *A* would be set at 20,000 kw per one-tenth cycle and at *C* for 5,000 kw per one-tenth cycle (the systems on the ends are on ordinary tie line bias; the cascade applies only to intermediate systems). System *B*, if it measures and controls only the tie toward *A*, would be set at 20,000 kw per one-tenth cycle (the sum of its own and system *C*'s natural bias); or if it measures and controls the tie toward *C*, it would be set at 35,000 kw per one-tenth cycle. Assume this latter case and assume a sudden new load of 20,000 kw appears on system *A*. The deficiency of generation is now 20,000 kw which is enough to reduce the speed of the whole group by half of one-tenth cycle. System *C* at this reduced speed has an excess generation of 2,500 kw which flows toward *B*. Its controller correctly makes no move. System *A* also at the reduced speed has a deficiency of 10,000 kw which it pulls over the tie from *B*. Its own controller, however, will call for an increase of 20,000 kw, which is proper. System *B*, with its large bias (see Figure 6) and noting only the tie in the direction of *C*, will call for an increase of 20,000 kw on its own generators (point 6), even though it is in no way responsible for the disturbance, and would do nothing if normal bias were used with net metering (point 7). Theoretically *A* will make the proper correction and restore equilibrium without the generators on system *B* ever making the full adjustment. However, some contribution will be made both on *A* and on *B* which will call for further corrective moves later. Speed of response to controller demands is important. In effect, the cascade system makes every intermediate system underwrite and guarantee the correction not only of its own load but of every load on the far side of the tie which is controlled. The system therefore is bad and cannot fail to upset smooth operation. Only where the more remote systems are insignificantly small and the metering complicated can it be justified.

Miscellaneous Operational Considerations

Speed of Response

Automatic operation with a tie line bias, such as has been discussed, and with no station anywhere on the interconnection acting as master frequency controller, has the operational advantage that it eliminates completely all the difficulties previously experienced with varying speeds of response. In the past it has been felt, and probably with justice, that some controllers, being more sensitive than others, make corrections which should be made elsewhere and thus do extra work and require later readjustments. By operating along a generation-frequency line, the time element disappears since each system will stop its correcting as soon as it reaches its own line with no reference to whether or not any other system has completed that part of the adjustment which falls to its share.

Effect of Operating on Wrong Generation–Frequency Line

Because at any instant it is difficult to determine the exact slope of the generation–frequency line, it may be expected in practice that many cases will occur when the bias controller is set improperly. It is worth while to consider what happens in such an instance. Figure 7 illustrates one example. The same buying and selling systems are represented but each of their controllers is set with a slope which is twice the true value in kilowatts per unit speed change. Conditions at point *A* are the same as those used previously in point 3. The analysis is simple because the buying system in the first instance believes itself to be on a proper slope and, therefore, does nothing. The selling system imagines it should drop 40,000 kw instead of the proper figure of 25,000 kw. (Note that the controllers on the combined systems believe that the excess generation is 40,000 kw instead of the true figure of 20,000 kw. The seller assumes the whole error to be on his end of the tie line.) Luckily, all the correction is not made at once, and if, for instance, the first correction amounts to 10,000 kw, conditions will reach point *B* as the actual response will be in accordance with the true (but unknown as far

Figure 5 (left). "Blocking" or "selective frequency" conditions on the purchasing system

Figure 6 (right). Cascade setting conditions on system *B* after added load comes on system *A*

Figure 7. Conditions existing when controllers are set for wrong amount of bias. First two steps only are shown, subsequent steps will spiral in toward point 0

as the controller is concerned) slope. At this point the selling system still feels that more correction is necessary and the buyer also has been jolted into activity. From here on, the condition, as a result of any given correcting impulse, becomes a matter of chance; that is, it depends on which controller gets its work in first. However, one point is clear, and that is that gradually the combination will trend (probably in a spiral) toward a proper correction at the point where the true and the controller setting slopes cross; that is, at proper speed and schedule. The process may be long and may require extra moves to compensate for some that are made in the wrong direction.

As a special case of a controller with an erroneous setting, we may list either flat frequency or flat tie line control. In the case of Figure 7, the errors in setting caused no particular inconvenience. The worst conditions are those which occur when the operating point lies in the shaded segment, that is, between the true slope line and the controller setting. In this case, one system always will make the wrong move. Correction in the proper direction will come eventually because it is not possible for two controllers to find themselves simultaneously in the shaded sector but errors will be made, initially. The net result of this situation in practice is

1. **Errors in setting obviously tend to be less serious as the speed or tie line errors approach the vanishing point because the error sector narrows down to a point.**

2. **The slope setting on any controller should not be considered as a fixed proposition to be established and forgotten, but should be subject to prompt adjustment under the direction of the system dispatcher who will determine largely from experience and trial and error the value which produces the best results at a given time.**

Action in Time of Trouble

When an emergency occurs in which a substantial block of generation is suddenly lost, power flow will readjust itself faster than any automatic equipment can hope to keep up with it. We need consider only what happens shortly afterward when the control has had a chance to come into action. If the buying company loses capacity and the speed drops, the condition will result in "over schedule in." The selling company is likely to find itself in the shaded segment shown in Figure 3 (point 4 is illustrative) where its automatic control also will drop and make matters worse. The same situation exists if the seller loses capacity. The buyer then finds himself with low speed and "under schedule in," as at point 5, and drops generation in his shaded area. These two situations, happily infrequent, are examples where desirable response would be based on speed only without consideration of the tie line, and thus the uncontrolled governors which may come into action, in all cases, will help rather than hinder. The practical answer to this possibility is perhaps simpler than it appears to be because on large interconnections it is rare that the loss of a single unit, however suddenly, will result in a sustained speed drop of as much as one-tenth cycle. It might be desirable because the speed actually is held within fairly narrow limits to have all automatic control cut out when speed errors as large as say 0.15 cycle exist. Such a remedy should be approached cautiously if it is usual to run the tie line with a schedule nearly up to its limit, because the invitation to overload which is implied when tie indication is cut off from the controllers may cause the line to trip and thus cease all usefulness.

Manual Adjustments of Generation

At times when the load is changing rapidly and occasionally at other times, it is necessary to make generation adjustments on units which are not under automatic control. It generally is believed that these adjustments are a major cause of tie line irregularities as well as speed errors. There is a common standing rule which says that no adjustments of generation ever shall be made in a direction which increases an existing speed error. This rule should produce good results unless the system in question finds itself in one of the cross-hatched segments shown in Figures 2 and 3. A more accurate operating rule would be never to drop generation below the frequency–generation line or raise it in cases above the line, but this is not practical unless tie line indication can in some manner be made available to all stations. There are two reasons why the present rule is not fully successful.

1. **With the best good will in the world, an operator who has been ordered to raise a generator 10,000 kw will not take the time always to do it properly if the speed shows slight rising tendencies.**

2. **Most station frequency indicating instruments are not sufficiently accurate to show what the speed really is when close to 60 cycles.**

It is suggested that in addition to having better indicating instruments in our stations, it might not be too farfetched to have the synchronizing motor control switches wired through a raise or lower block on some accurate frequency indicator (possibly of the electronic type). In this way correcting impulses would be applied only when the system required them. The operator would be relieved of tedious waiting and the effect on the system would be much improved.

Governors

It is possible after a consideration of the requirements for control as outlined in the foregoing text to draw certain conclusions as to what is desirable in a governor.

1. **A fairly steep drooping characteristic to**

prevent wandering and unwanted assistance based on speed indications alone.

2. If the governor could come into action quickly on errors above 0.10 or 0.15 cycles, it would help to sustain the system in time of trouble. Therefore, there is some argument for a droop characteristic which would be steep when close to 60 cycles and quite flat as the error gets larger.

3. The dead band certainly should be held to a minimum.

4. There should be a quick and positive response to whatever means is provided for moving the droop characteristic parallel to itself as is done with the synchronizing motor. Studies made on various systems around the country have demonstrated that the synchronizing motor is far from perfect for this purpose since its response is neither definite nor uniform under all conditions.

Conclusions

1. The slope of the speed–generation line measures the power required to produce a definite variation in system speed.

2. The line may be used in conjunction with the deviation from schedule of a tie line to indicate the magnitude, direction, and location of the corrective effort needed to restore both speed and tie to schedule.

3. The method is applicable to complex as well as simple interconnections.

4. The method lends itself readily to the use of automatic equipment under the name tie line bias.

5. Tie line and speed control by this method, being definite, eliminates the disturbing feature of different control systems having different speeds of response.

6. The slope of the generation–frequency line for any particular system is not constant, but variable with load conditions.

7. A flat frequency master controller is a liability on an interconnection where biased tie line controllers are in operation.

8. Prime mover governors, sensitive to speed only, and free to act, are not conducive to steady speed and tie line conditions. They are troublesome in proportion as they are more nearly isochronous.

9. Automatic control of tie lines by selective frequency is not as effective as by tie line bias.

10. Tie line bias with cascade settings is generally unsatisfactory.

11. In time of system trouble caused by sudden loss of capacity, controllers sensitive to frequency only would be helpful were it not for the danger of overloading and tripping out of interconnecting tie lines.

12. A blocking relay is suggested to prevent manual generation changes from being made in such direction as to increase a frequency error.

13. Under normal conditions, governors not under the control of automatic tie line equipment should be relatively insensitive.

14. Governors under the control of automatic tie line equipment should respond definitely, quickly, and uniformly, over full gate range.

Discussion

C. N. Metcalf (Consolidated Edison Company of New York, Inc., New York, N. Y.): These comments are to suggest a simple method of determining the frequency–generation line described by Robert Brandt in his paper. In this method, the approximate frequency–generation line for any system can be determined without isolating that system from the rest of the interconnection.

The Consolidated Edison Company of New York, Inc., is using Leeds and Northrup load-frequency control equipment to control the load on its ties to the Northeast Interconnection (Consolidated Edison, Niagara Hudson, and New England Power Companies). For the most part, tie line bias control is used.

The Leeds and Northrup load-frequency control equipment records frequency and the deviation of tie line load from a scheduled setting. By a detailed inspection and matching of these two charts, a number of points of coincident and abrupt changes in tie line load and frequency were selected which reasonably could be assumed to have been caused external to the Consolidated Edison System.

By Brandt's terms, Consolidated Edison was the "selling company" with scheduled tie line load out for the points selected. Thus an abrupt decrease in tie line load (out) and a coincident increase in frequency would be caused by excess generation external to the Consolidated Edison System. The amount of load rejected by the tie line has the same effect as adding this amount of generation to the Consolidated Edison System and would result in the same increase in frequency.

Similarly, an abrupt increase in tie line load and a coincident decrease in frequency would be caused by a deficiency of generation external to the Consolidated Edison System. The amount of increase in tie line load (out) would have the same effect as dropping this amount of generation by the Consolidated Edison System and would result in the same decrease in frequency.

This method of determination is based on careful selection of the points of coincident changes so that load and generation changes, for the system being studied, will be negligible. The selected points were within the frequency band of 59.85 and 60.15 cycles in which there would be little if any governor action. Also frequency changes of less than 0.05 cycle could not be used with any reliability.

As the points of coincident changes selected were at different hours of the day and for different days over a 2-month period, the total system generated load at these times varied considerably. Therefore, the measured changes in the tie line load were adjusted to a common base of 1,500 megawatts total generation for plotting purposes.

The average line drawn through the points of adjusted tie line load change plotted against corresponding frequency change, indicates a frequency–generation line of 30 megawatts per 0.1 cycle for 1,500 megawatts load on the Consolidated Edison System. This may be high, as previous papers have indicated a value of about one per cent of system load per 0.1 cycle as compared to two per cent determined by this method with the limited number of cases to date. However, the grouping of the plotted points is such as to indicate that this approximate determination is fairly close for the Consolidated Edison System.

The optimum bias setting for tie line load bias for any system depends on a number of factors such as fluctuating railroad load, system and tie line capacities, speed of response of the governors and servo mechanisms to load-frequency control impulses. The optimum setting undoubtedly will be determined after trial operation at various values. However, an approximate determination of the frequency–generation line should be very helpful in deciding on the optimum bias setting.

G. S. Lunge (General Electric Company, Schenectady, N. Y.): This paper is one of the most complete analytical treatments of this subject that has appeared in the English language and, despite its modest title, contains many practical suggestions that undoubtedly are based on actual operating experience.

The author suggests that even at generating stations not containing any automatic load-frequency control equipment, blocking relay equipment (possibly of electronic type) would be very helpful in preventing injudicious manual adjustment of generator output by the operator.

Such equipment is already available commercially and can be arranged readily to block "raise" impulses to the governor synchronizing motor from the control switch (or switches), if the system is operating above the desired frequency/net kilowatt interchange characteristic line by a definite amount, and to block "lower" impulses to the governor synchronizing motor, if the system is operating below this characteristic line. This relay equipment consists essentially of a ratio type milliammeter actuating (without use of actual contacts) two electronic relays controlling interposing relays in the governor synchronizing motor control circuits. One winding in the ratio type milliammeter is supplied with a direct current proportional to the frequency as measured by a photoelectric recorder, and the other winding is supplied with a direct current proportional to the totalized tie line load, as totalized at the area load dispatcher's office.

The least expensive arrangement using this blocking relay equipment is to install it only at the area load dispatcher's office, and transmit, as required, "block raise" and "block lower" signals to the manually controlled generating stations. Where dis

tances are large, this can be accomplished conveniently by a frequency-shift carrier-current load control channel, which is capable of sending either of two types of signals (or neither signal), as required.

At a later date, if an automatic frequency controller is substituted at any station for manual control of its output, these same blocking impulses can be used in a similar manner to selective frequency control, to prevent undesirable action on the part of the controller, but without the disadvantages of the usual selective frequency control to which the author calls attention.

Such an arrangement is less expensive than providing a tie line load biased frequency control equipment at each generating station, biased by the area net tie line load interchange as telemetered to each station from the area load dispatcher's office. It also will be recognized that it is applicable to any type of frequency control equipment that operates via the governor synchronizing motor of the prime mover. This system also provides fully centralized automatic control in the hands of the area load dispatcher, thereby relieving the individual generating station operators from having to readjust the bias settings in their individual generating stations in accordance with telephoned instructions from the dispatcher.

E. E. George (Ebasco Services, Inc., New York, N. Y.): This paper, in spite of the first word in its title, presents a very practical analysis of many controversial features of interconnected system operation. Many of the present-day conflicting opinions result from overemphasis of only one side of the argument. The conclusions in this paper may need further comment.

Conclusions 3 and 4 might be combined in the statement that net bias load control is always highly advantageous and on complicated systems is almost essential to satisfactory operation.

Conclusion 6 is a further argument for net control because variable bias with load conditions is hardly practical unless the bias setting for each system is independent of other systems.

Conclusions 7 and 8 well might be qualified by emphasis on the fact that they are based on normal operating conditions. In emergencies flat frequency controllers and speed sensitive governors have important advantages. In the case of systems with weak tie lines or poor manual handling of block changes, emergencies are more or less routine, and proper operation of governors is almost indispensable.

A few further conclusions appear desirable to bring out the results of the analyses in the paper.

1. Most of the small continuous swinging of load on tie lines is caused by differences in governors as to dead band, slope, and speed setting.

2. Most of the sudden load changes on tie lines are caused by block load changes made manually to keep automatic regulating units within range.

3. Many of the large drifts in load on tie lines are caused by either insufficient maneuvering range on regulating plants or poorly co-ordinated block changes, or both.

4. A governor with large slope will operate the overspeed shutdown device if all load is lost, delaying service restoration.

5. Base load control would be helpful in keeping governors normally off of straight speed control and yet permit them to act promptly when the frequency goes outside of predetermined limits. Safe emergency performance cannot be obtained by blocking governors, crowding limit springs, or using gate limits. Such things tend to make emergencies more serious than necessary.

6. The most effective means of general improvement of tie line operation is to place more units in each plant under automatic tie line control and to place more plants on each system on automatic tie line control. This not only increases speed of response and range of response but also reduces block changes and leaves fewer governors on straight speed control.

7. The characteristics of system load may be determined by blocking all governors and opening a loaded tie line. Similar tests may be made with some of the governors in service, and by subtraction the effective regulation of the governors can be approximated.

Robert Brandt: In various discussions of the method of tie line bias the idea frequently is brought out that it permits, or even more definitely that it provides, a "contribution" to a neighbor who may be in trouble. There is an implication that something extra is done to provide support in such a condition. This statement should be clarified. The support is there but the extra is not. An examination of Figure 3 will show that a selling company will go "over schedule out" during conditions of low frequency while it is still operating on its own speed-generation line; that is, when the speed is low the selling company satisfied to supply to its neighbors on a net basis more power than had been scheduled. Such a situation comes about quite naturally and not from any altruism inherent in the control equipment. When the speed on the interconnection is low the amount of generation which would be sufficient to carry the load of the selling system at 60 cycles becomes more than enough at a figure less than 60 cycles, and the difference is the amount which goes out over the ties, and has given rise to the "contribution" idea. Similarly, a buying company operating on its speed-generation line, with its controller making no corrective move, is satisfied when it is taking less than its desired schedule, if the speed be low.

Parallel Operation of Aircraft Alternators Using Electronic Frequency Changers

O. E. BOWLUS

Synopsis: This paper reports initial work on an electronic method for operating several main aircraft engine driven alternators in parallel to supply the electrical loads of an airplane. This would make unnecessary any mechanical constant speed drive for each generator. An electronic frequency changer is associated with each alternator and the outputs of the changers paralleled at the load bus. Synchronization, load division, and provision for reactive power are discussed, and test data obtained from two 4-kva units are presented.

As a result of the considerable increase in the size of military aircraft and the subsequent necessity for larger power driven equipment, great changes were made in recent years in the requirements for electric power in large airplanes. It soon became apparent that the 24-volt d-c systems were not adequate because of the considerable weight penalty imposed by the size of the conductors required to carry the power loads. This led to the consideration of higher voltage systems and also the use of alternating current.

These considerations have been examined and reported in several papers.[1,2] As shown in another paper,[3] the power system for large military aircraft was standardized upon as 400-cycle alternating current, three phase, 208 volts line to line. An initial move has been the development of a 40-kva alternator unit to replace the d-c generators previously used.[4] However, as several alternators must be used to provide the necessary electric power on large military aircraft, the parallel operation of these alternators presented new problems which had to be solved before the new a-c generators could be brought into full use.

Among the requirements to be fulfilled were the following:

1. Parallel operation of alternators into a common load bus.
2. Automatic division of load between alternators.
3. Provision for cutting out a defective unit without disturbing the others.

The first requirement can be met easily provided the alternators are driven at the same speed. However, as it was desirable that, in the case of large military aircraft, the generators be driven by the main engines, this introduced a serious problem. Because of the variations in the rotating speed of the airplane engines, parallel operation of the generators was impossible unless some means were introduced to either

1. Provide a variable speed mechanical drive between the engine and alternator, with a governor to maintain constant alternator speed; or,
2. Drive the alternators at variable engine speed and change the variable frequency output from each alternator to a constant frequency for paralleling.

As no satisfactory variable speed drive was available at the time, and since a frequency changing unit, in addition to permitting synchronization of the alternators, also could be designed to meet requirements 2 and 3, such a unit appeared to offer desirable features for the parallel operation of the alternators.

Description of Frequency Changer

The electronic frequency changer is in essence an electronic commutator which accomplishes the conversion of power with a wide range of input frequencies to a constant output frequency.

Functionally, the device has two distinct circuits, a power circuit and a control circuit. The power circuit accomplishes the actual frequency conversion and has associated with it the voltage regulating circuit, the load division circuit, overload protection, and the necessary control circuits for starting the device and applying load. The control circuit establishes the output frequency, provides the necessary phase displacement of control signals to the power circuit to establish a 3-phase output, and incorporates the necessary circuits for synchronizing two frequency changers.

Regulation of average line output voltage is accomplished by controlling the excitation of the alternator supplying input power. This excitation control is accomplished by a carbon pile regulator. Since the output frequencies of units operating in parallel are maintained exactly in step by interconnection of the oscillators which determine the output frequency, circulation of reactive current between units is not a problem and load division is accomplished by controlling the relative excitations of the alternators supplying the units. This function is performed by a load equalizer network which is energized when the units are operated in parallel.

For an airplane installation, the units would be connected as shown schemati-

Paper 47-5, recommended by the AIEE committee on air transportation for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted May 1, 1946; made available for printing October 23, 1946.

The work described in this paper was performed under a contract with the Air Technical Service Command. The authors are indebted to the Air Technical Service Command and Chrysler Corporation for permission to publish this paper.

cally in Figure 1. The generator may be mounted directly on the engine if an adequate pad is available and vibration not too severe, or driven by a power take-off shaft; the frequency changer would be in the nacelle and would be connected to the main power lines running through the wing to the fuselage. Other wires would be connected to the necessary meters and control switches at the flight engineer's station.

Electronic frequency changers have been used on public utilities systems for a nonsynchronous tie[5] but for aircraft applications some differences in the control system and the number of power tubes used are desirable. These differences permit operation of any one changer alone and without rotating equipment floating on the line.

Figure 2. Power circuit 1 suitable for supplying either 3-phase or single-phase constant - frequency power from a 3-phase variable - frequency source

Description of Test Unit

At the request of Army Air Forces, experimental work on a pair of 4-kva units of this type was undertaken. The 4-kva size was chosen as representing the largest unit which could be built at reasonable cost with commercially available tubes.

For laboratory purposes two 30-volt 11-kva alternators were used because of their availability and a 3-phase step-up transformer was used to supply the necessary voltage to the tubes. For convenience, the control circuit and power tube filaments were supplied from a 115-volt 60-cycle source.

Two different power circuits were built and tested. The first one, Figure 2, has relatively simple current paths and current flows through only one tube in series. It is in essence three independent single-phase frequency changers and is of especial interest if only single-phase output is needed. The circuit is of the parallel inverter type.[6]

Less favorable characteristics of the circuit for this purpose are as follows:

1. High values of direct current through the input neutral introduce I^2R losses in the step-up transformer (or in the alternator if the step-up transformer is eliminated).

2. A low power factor is presented to the step-up transformer and alternator.

3. Requires an output transformer as well as inductive reactors.

The net result is increased weight and lower efficiency as compared to power circuit 2.

When capacitors are connected in series with the output lines, the circuit performs about as well as circuit 2. The tube peak inverse voltage is higher and some difficulty was experienced from this standpoint when operating at heavy load and when applying or removing heavy loads. Tube service is not as severe with power circuit 2.

Power circuit 2, the one finally adopted, is shown in Figure 3. This specific circuit embodies suggestions by J. Boyer of the Westinghouse Electric Corporation. This circuit uses three center-tapped reactors to replace the output transformers and commutating reactors. Its operation is discussed in the appendix. The necessary capacitors and the voltage regulator circuit also are shown. Figures 4 and 5 show the interior of this unit.

Voltage Regulation

A 30-volt d-c type carbon pile regulator was used with a 3-phase step-down transformer and a 3-phase selenium rectifier.

When used with aircraft d-c generators, the tendency for the carbon pile regulator to flutter at low values of field current can be eliminated by careful adjustment of the stack pressure. For this application, the flutter could not be adjusted out. An antiflutter circuit consisting of a small transformer, an electrolytic capacitor, and a resistor was designed to produce a magnetic pull on the regulator armature out of phase with the pull tending to produce flutter. Little difficulty with flutter was experienced thereafter.

Overload Relays

Instantaneous relays connected directly in each of the three input lines from the step-up transformer were used to protect against serious faults but not against sustained overload. Although an additional thermal delay relay could be used to protect against sustained overload, none was used in these experimental units, the d-c ammeter being sufficient to warn

the operator when he is overloading the tubes.

Control Circuit

Although a number of circuit variations were tried, the same general outline was followed throughout the development. The biggest improvement came with the substitution of vacuum tubes for gas tubes wherever possible. Vacuum tubes have proved to be inherently more stable for this application. The control circuits as built up for experimental purposes are shown in Figures 6 and 7.

The 400-cycle output frequency is determined by a single-tube *884* saw-tooth oscillator operating at 2,400 pulses per second. Output from this tube controls a 3-tube *6J5* switching or counting circuit in such a manner that the three tubes fire in sequence, each 800 times per second. This is the method used to obtain 120 degrees displacement between phases of the output frequency. Each of the three *6J5* tubes controls a pair of *6V6GT* tubes in a flip-flop circuit wherein each tube passes plate current one half of the time. When one tube is "on" the other is "off." The "on"-"off" relation reverses with each pulse from the *6J5*. The period between reversals represents one-half cycle of the output frequency.

The square wave output voltages from the flip-flop circuits are transmitted through transformers to the grids of the *FG-67* power tubes. A square wave input to the grids is desirable because each of the power tubes must be able to start passing plate current at any point during a half cycle. To insure that the tube will be ready to pass current when the plate becomes positive with respect to cathode, the grid must be held in conducting position for the full half-cycle. On the next half-cycle, the same grids must be held sufficiently negative to prevent flow of plate current for the full half-cycle.

Transformer coupling must be used between control circuit and power circuit because the cathodes of the various power tubes cannot remain at the same potential. Some difficulty was experienced in keeping transient voltages set up by the opening of contactors from getting back into the control circuit, causing the two control circuits to drop out of synchronism. Placing small capacitors across the contactor hold-up coils eliminated this trouble. Any change in load on the control circuit such as turning the power circuit on or off or failure of power tubes to commutate has an effect upon the stability of the flip-flop circuit. This effect was minimized by placing a resistance load across the primary of each transformer in the flip-flop circuit such that a change in driving power to the grids of the power tubes represents a small change in total load on the flip-flop circuit.

Synchronization

Three separate components of the control circuit must be synchronized with corresponding components in the second control circuit.

Figure 4. A 4-kva electronic frequency changer

Front view with outer panels removed

Figure 5. A 4-kva electronic frequency changer

Top view with outer panels removed

1. First the *884* oscillators must be synchronized. A portion of the plate saw-tooth signal is fed from each tube to the grid of the opposite tube. The resulting frequency will be equal to that of the fastest circuit rather than an average of the two. These connections are permanent except when it is desired to operate one unit entirely separate from the other. A dummy connector plug then is used in place of the synchronizing cable.

2. Next, the 3-tube *6J5* counting circuits must be synchronized. By means of an auxiliary tube, a signal is fed from the plate of a *6J5* tube in one circuit to the grid of the corresponding tube in the other circuit. A switch momentarily is closed to obtain synchronization.

3. Finally, the 6-tube *6V6GT* flip-flop circuits must be synchronized. The six tubes in each circuit are maintained in proper firing sequence by two small capacitors connected between screen of one pair and grid of another pair. There still remains the possibility of the six tubes in one circuit being 180 degrees out of phase with the other circuit. A small capacitor between a plate in one circuit and a grid in the other brings them in phase by closing a momentary-contact switch.

A single double-pole momentary-contact switch performs synchronizing operations 2 and 3 simultaneously. No synchronizing lamps are necessary—merely flip the momentary contact switch when in doubt.

Parallel and Series Capacitors

By parallel capacitors are meant the capacitors which are connected either line to line or line to neutral across the output of the frequency changer. These may be connected either on the tube side or the load side of the three series capacitors one of which is connected in series with each output line.

The purpose of both the parallel and the series capacitors is to assist in the commutation of current between the power tubes. The grid of a thyratron tube can be used to prevent or control the instant of start of plate current flow, but once the plate current is flowing, other means must be provided to turn off the current. The capacitors provide this means by causing the plate to go negative at the instant the grid is made negative and remain negative for a time sufficient to deionize the tube. After this delay of a few microseconds, the grid again regains control. More detailed explanation is given in the appendix.

Figure 6. Control unit for 4-kva electronic frequency changer

The capacitance is determined by the operating requirements. Parallel capacitors are desirable for light loads while series capacitors are more effective for heavy loads. Since the load current flows through the series capacitors, the capacitive volt-amperes supplied by them increases with load, whereas the capacitive volt-amperes supplied by the parallel capacitors remain essentially constant. At no-load open circuit, the series capacitors have no effect on the operation and the capacitive volt-amperes must be supplied by parallel capacitors. By reducing sufficiently the microfarad rating of the series capacitors, the changer can be made to function normally with the output terminals short-circuited together. In view of the fact that the voltage regulation within the changer suffers from a large reactive drop in the output lines, it is desirable to make the series capacitance as high as is consistent with starting heavy loads. In this aircraft application, the largest induction motor determines the size of the series capacitor.

For parallel operation of two changers, it was found desirable to connect the parallel capacitors on the tube side of the series capacitors and to keep the micro-

farad capacitance of the series capacitors as high as possible. This will be discussed under parallel operation.

Contrary to expectations, the capacitors need be neither large in physical size nor heavy. Standard oil-filled 60-cycle capacitors of normal voltage rating appear to stand up on 400 cycles without excessive heating. However, no extended life test was made. To provide maximum cooling surface per microfarad of capacitance (in the case of the parallel capacitors), a number of small units were connected in parallel to make up the total desired capacitance. With forced air cooling, the size and weight no doubt could be reduced further. It is estimated that the weight could be reduced to approximately one-fifth the total active weight of the changer.

To increase the efficiency of the changer at light loads, a portion of the parallel capacitance can be connected permanently across some of the individual heavy loads.

Parallel Operation and Load Division

Parallel operation is accomplished by synchronizing the two control circuits so that the output signal of one is exactly in phase with the other. When this is accomplished, the output contactors may be closed onto the 400-cycle bus. Synchronization of the control circuits is accomplished by the flip of a momentary-contact switch.

The test units as built must be paralleled at no-load or when the load on each is approximately the same, because of the action of the series capacitors. When the load is identical on both, the output terminal voltages are exactly in phase. When one is unloaded and the other loaded, the terminal voltages are no longer in phase. The power tubes are fired in phase but the load current through the series capacitor on the loaded unit causes the terminal voltage on this unit to lead the terminal voltage on the unloaded unit. The greater the differences in load, the greater will be the change in phase. When the load on the one unit becomes greater than approximately 2,500 volt-amperes, they cannot be paralleled successfully. This is another reason why the capacitance of the series capacitors should be made as high as possible.

In connection with the foregoing, it was found desirable to connect the parallel capacitors on the tube side of the series capacitors. With them on the load side the drop across the series capacitor is increased further, interfering that much more with parallel operation.

For motor loads it might be possible to place part of the series capacitance between the output terminals and the motor where it would not interfere with parallel operation. A combination of series and parallel capacitance might be chosen such that the motor would operate at its rated voltage.

The first attempt at load division was to place a current transformer in each of the output lines. A voltage proportional to load, obtained from the drop across a resistor in one of the secondaries, was applied across a resistor in series with the corresponding phase of the primary of the voltage regulator step-down transformer. All three phases were so connected, the resistors being inserted at the neutral of

the Y-connected primary. Wires were connected from the step-down transformer in one changer to the step-down transformer in the other changer to obtain cross-compensation. This system worked well at heavy loads but was not satisfactory at light loads. One changer would tend to drive the other.

The tendency for one unit to drive the other was overcome by placing the current transformers in the input lines to the changer just after the step-up transformer. The alternating current from the three single-phase current transformers is rectified with a 3-phase rectifier into a resistor, the direct voltage being proportional to input load. Load division and cross-compensation then are accomplished by connecting to a compensating coil in the voltage regulator (see Figure 3).

Inductive Loads

The units operate satisfactorily with static inductive load providing there is sufficient capacitance in the circuit to insure commutation of the tubes. Conceivably, enough capacitance could be connected permanently into the units to take care of any inductive load, no matter how large. However, to reduce circulating reactive current and obtain reasonably good efficiency at light and medium loads, it is desirable to provide only enough capacitance within the unit to handle medium loads.

Motor Loads

Motors, from the standpoint of being an inductive load, present no special problem. Capacitors, when needed, can be connected across the motor for power factor correction.

Motor operation was found to be unstable and erratic. The motor will come up to normal speed, then immediately drop to a low speed, then rapidly rise again, and so on. This fluctuation in speed goes through a cycle in a second or less, depending on the amount of resistive load—the lower the resistive load, the more rapidly the speed fluctuates. The fluctuations will continue indefinitely unless sufficient resistive load is added to damp them out.

This unstable operation is not peculiar to the frequency changer or to 400-cycle frequency. The same difficulty has been experienced on 60-cycle power when operating induction motors with series capacitors connected in the supply circuit.[7] Elimination of the series capacitors and use of parallel capacitors alone will not remedy the trouble. Since capacitors are necessary to the operation of the changer, the only means of eliminating the unstable condition appears to be to damp it out. Resistive load being small in comparison to induction motor load on aircraft makes it necessary to achieve damping with a minimum of resistance to prevent undue waste of electric energy.

A 3-horsepower motor requires approximately 2,400 watts resistive load when operated from one frequency changer, and approximately 4,800 watts resistive load when operated from two changers in parallel. This load, of course, can be lamp load or some other useful load in the airplane.

Neutral for 4-Wire System

An artificial neutral must be provided to obtain a 4-wire, 3-phase system. Either Y-connected inductive reactors or capacitors may be used for this purpose, but capacitors were found to be more desirable. Inductors, if used, present an inductive load to the changer thereby requiring additional capacitance. Zigzag connection of the inductors was found desirable to stabilize the neutral. By connecting the parallel capacitors line–neutral rather than line–line, no additional capacitors are required for power factor correction. The capacitors, in addition to providing the same degree of stability of the neutral, do not carry a weight penalty.

At best, the artificial neutral will handle only a small single-phase load without unbalancing both line–line and line–neutral voltages.

Weight

Because these units were intended for laboratory test only, no attempt was made to make them with minimum possible weight. Each unit weighs 245

pounds. With forced air cooling and lightweight design, it is estimated the weight could be reduced to approximately 70 pounds. It also has been estimated that a 40-kva unit might weigh 300 pounds.

Test Results

Two units were built and operated satisfactorily in parallel. Each unit has its individual control circuit and the control circuits were synchronized for parallel operation by pushing a button. Load division was accomplished very easily.

Heavy resistive loads could be handled under all conditions. Inductive loads larger than approximately 1,250 volt-amperes per unit required power factor correction for satisfactory operation. Power factor correction can be accomplished by adding small capacitors across the inductive load.

A single unit or both in parallel would start and operate a 3-horsepower induction motor, provided a large resistive load was already on the line or applied with the motor. One-quarter-horsepower motors operated satisfactorily without additional resistive load and without power factor correction. Large motors required power factor correction and the presence of sufficient resistive load to stabilize operation.

While the test circuit had only one-tenth the volt-ampere capacity that probably could be used in an airplane, some of the test results are of interest in indicating the trend of the performance. One such test was variation of alternator speed; input frequency was varied from 300 cycles to 900 cycles with negligible effects on output frequency, voltage, and watts. Load division data were taken with one unit operating at a 450-cycle input frequency and the other unit at 300, 500, 700, and 900 cycles successively. Frequency of incoming power seemed to have no noticeable reflection on the ability of the units to share load; however, the load division did display a tendency to drift at times as the voltage regulators heated up.

When the input frequency becomes equal to the output frequency, only 12 of the 18 power tubes transmit power. This means that the tube size has to be chosen with this in mind or else the generator drive ratio chosen with respect to the operating speed range of the engine to minimize operation at these input frequencies. At other speeds, the division of load between tubes is good and substantially independent of individual tube characteristics. In fact, any one power tube can be removed from the circuit bodily with only minor effects on the output. This argues well for the reliability of the circuit.

As the experimental unit used a step-up transformer to raise the alternator voltage to the necessary value, and also as the filament and control power were supplied from a separate source, the most useful efficiency figure is the ratio (output watts)/(transformer output watts+filament watts+control circuit watts). This figure most nearly reflects actual operating conditions. This efficiency is shown in Figure 8 for power circuit 2 with resistive load. Loads of lower power factor seem to make only small changes in these values. This is probably caused by the effect of the large fixed loss—410 watts for filaments, and 210 watts for control—or a total of 15 per cent of the rated output.

A summary of the voltages, current, and powers in various parts of power circuit 2 is given in Figure 9. It is interesting to note that the voltage regulator markedly increases the input voltage to the changer, with increase in load, in order to hold the output voltage substantially constant, and that this increase is more than enough to compensate for the drop in the series capacitors. Table I gives some similar data for an inductive load as well as a resistive load.

Wave form of the output varies slightly with load. Figure 10 shows the wave form of one phase of the 400-cycle output under three operating conditions and also the voltage applied to the grid of one of the tubes.

Possible Future Development

The test circuit was built as a scaled-down model of a 40-kva unit. A full size frequency changer presumably would be operated directly from an alternator designed for the purpose, and no step-up transformer would be required. Also, an auxiliary alternator probably would be used to supply filament heating power and the various voltages required for the control circuit. Further savings in tube size and weight of some components might be achieved by using a higher voltage (and hence reduced current) in the power tube circuits. This would be more convenient using power circuit number one as it has provision for stepping down the output voltage to the standard 208 volts.

For some commercial aircraft with large single-phase loads, such as lighting, radio, and cooking, it might be advantageous to consider a complete single-phase system using capacitor type motors. For use with an electronic frequency changer, this would give a relatively high power factor load suited to a 6-tube changer of the type of circuit 1. In view of the simplicity of the power and control circuits, this is an attractive possibility. While single-phase loading of a conventional generator is not desirable, the interposition of a frequency changer distributes this single phase load equally among the three phases of the generator, reducing the weight penalty to be expected for a single-phase system. There is also some saving in cable weight caused by the lesser amount of insulation in a single wire ground return system.

Appendix. Principle of Operation of Power Circuit 2

For convenience, the 18 power tubes of Figure 3 may be divided into six groups of three each. Two such groups may be associated with each phase of the constant frequency output. In each phase, one group has the three anodes connected together to one end of a center-tapped reactor; the other group has the three cathodes connected together to the other end of the reactor. For each output phase group, each line of the variable frequency input is connected to one of three cathodes of one tube group and to one of three anodes of the other group. In each phase, a voltage is fed to the control grids of the two groups of three so that they are 180 degrees out of phase with respect to each other. This voltage is supplied in the form of a square wave with the result that in each phase the grids of one group of three tubes are held positive with respect to the cathodes while the grids of the other group of three tubes are held negative. The square wave being supplied at 400 cycles, each group of three tubes is made to pass current for a half cycle of the output frequency and to block passage of current the succeeding half cycle. All three phases receive identical control voltages except that the square wave to each phase is displaced 120 degrees from the other two phases.

Referring now to Figure 11, at instant t_1

(a). Tubes in group 2 rendered nonconducting.
(b). Tubes in group 1 rendered conducting.
(c). Tubes in group 5 are conducting.
(d). Tubes in group 4 are conducting.
(e). Tubes in group 3 are nonconducting.
(f). Tubes in group 6 are nonconducting.

Between instant t_1 and t_2

(a). Passage of current is from input lines A, B, and C through groups 1 and 5, left half of reactors 1 and 3, phase 1 and 3 of load, phase 2 of load, right half of reactor 2, group 4, and return to lines A, B, and C.

At instant t_2

(a). Tubes in group 5 rendered nonconducting.
(b). Tubes in group 6 rendered conducting.
(c). Tubes in group 1 are conducting.
(d). Tubes in group 4 are conducting.
(e). Tubes in group 2 are nonconducting.
(f). Tubes in group 3 are nonconducting.

Between instant t_2 and t_3

(a). Passage of current is from input lines A, B, and C, through group 1, left half of reactor, phase 1 of load, phases 4 and 6 of load, right half of reactors 4 and 6, groups 4 and 6, and return to lines A, B, and C.

This process likewise may be traced through for instants t_3, t_4, t_5, and t_6. Instant t_7 is identical to t_1, and the cycle repeats.

It may be observed that while group 1 is conducting, current will pass through the tube connected to the input line which is most positive. As the voltage on this line falls below that of another line, the current automatically changes over to the tube connected to that line. The three tubes act as rectifiers of the input voltage to supply unidirectional current to the left end of reactor 1 during every other half cycle of the output frequency. Obviously, the input frequency is not dependent in any way upon the output frequency and vice versa.

The capacitors shown connected line to line across the output assist the center-tapped reactors in commutating the current from one group of three tubes to the group of three tubes connected to the other end of the common reactor. Referring again to phase 1 involving groups 1 and 2, the left end of reactor 1 is negative with respect to the center tap an instant before the grids of group 1 change from negative to positive At the instant the grids of group 1 are made positive (and the grids of group 2 are made negative) the tube of group 1 having the most positive potential between plate and cathode, fires bringing, instantaneously, the potential of the left end of the reactor to a positive voltage with respect to the center tap by virtue of the low tube drop which exists when a tube is passing current. This sudden change of the left end of the reactor from a negative to a positive potential is transmitted by transformer action to the right end such that it changes the right end from a positive potential to a negative potential. This sudden drop in potential causes the plates of the tubes in group 2 to go negative with respect to the cathodes. The tubes of group 2 will be extinguished and the grids regain control providing there is sufficient capacity between output lines to enable the plates to remain negative with respect to cathodes long enough for the tubes to deionize. Lack of sufficient capacity between lines will give poor commutation, erratic operation, and will damage the tubes if the condition is allowed to persist.

Capacitors also are placed in series with the output lines to assist in commutating the tubes under application of heavy loads. A low capacitance is more effective in helping commutation than high capacitance. However, the capacitance must be made as high as possible, consistent with good commutation, in order to hold to a minimum the reactive drop in the output lines.

DISCUSSIONS of overvoltages that are produced by closing and opening capacitor circuits have appeared in several articles.[1-4] All the authors conclude that such overvoltages can be reduced by momentarily inserting resistors in series with the circuit as the circuit breaker opens to interrupt the charging current. Installations of 138-kv underground cable by the Department of Water and Power in 1943 provided an excellent field laboratory for capacitive-current switching. This paper describes and presents results of an investigation of problems incident to interrupting 138-kv cable charging current.

Tests were performed on the Toluca-Fairfax West circuit which is one of two 138-kv links between receiving station D and receiving station E. This circuit consists of five miles of 138-kv underground cable and seven miles of overhead line. Details of the underground cable may be obtained from reference 5. The charging current of this circuit is 80 amperes per phase at normal voltage.

The investigation was well under way when on August 26, 1943, a lightning arrester failed from overvoltage produced by de-energizing the Toluca-Fairfax East circuit from the receiving station E terminal. The arrestors are located at the junction between overhead and underground sections of the circuit and a voltage in the order of three times normal is required for breakdown.

The circuit breakers installed on this circuit are tank type, solenoid-operated and function on the dethermalizing arc-quencher principle described in reference 6. Switching tests without and with resistors in the circuit breakers are described in this paper and the final design of a step-type 800–2,000-ohm resistor is presented. A theoretical discussion of the effect of resistors in circuit breakers handling charging current is given in the appendix.

Conclusions

1. Transient overvoltages caused by arc restriking when switching capacitive circuits can be limited by resistors across the main contacts of circuit breakers.

2. A definite limitation is imposed upon overvoltages produced at the point of circuit interruption by the use of resistors (Figure 8). The limitation depends upon the ratio of the ohmic value of resistance used in the circuit breaker to the ohmic value of capacitive reactance of the circuit being interrupted (R/X_c).

3. Transient overvoltages which occur at the point of circuit interruption may produce higher overvoltages at other points on the power system as a result of amplification of the transient frequencies through system circuits.

4. Restriking on contacts interrupting resistor current does not cause overvoltages with ratios of R/X_c as low as 0.6 and probably does not cause overvoltages with ratios considerably below this value.

5. Increasing the speed of contact separation reduces restriking in the circuit breaker. It is doubtful if increased speed is justified from this standpoint alone as resistors definitely limit the voltage and the restrikes

do not put any undue stress on the circuit breaker.

6. A step-type resistor of 800–2,000 ohms can be added to existing circuit breakers on the cable circuits of the Department of Water and Power without replacing the existing arc quenchers, linkages, or operating mechanisms.

Resistor and Auxiliary Contact Design

The final design for installation in the circuit breakers on the cable circuits consists of an 800–2,000-ohm step-type resistor which, with the 1,000-ohm capacitive reactance of a 5-mile 138-kv cable, results in an R/X_c ratio of 0.8. The curves developed in the appendix and presented in Figure 8 show that this value of the ratio limits overvoltages to 1.5 times normal at the point of circuit interruption. Figure 1 shows the arrangement of the resistors and the necessary auxiliary contacts in the circuit breaker, and Figure 2 presents a schematic diagram of the electric circuit.

The step-type resistor requires two sets of auxiliary contacts for interrupting resistor current. The moving members of these contacts consist of bayonets attached to the circuit breaker crosshead. The bayonets slide into stationary contacts having spring pressure members at the bottom of the resistor tubes. The final or second auxiliary contact which interrupts the 2,000-ohm resistor current incorporates a built-in quick-break spring mechanism. The head on the bayonet tip catches on the spring contact as the crosshead falls in the opening stroke of the circuit breaker, thereby arresting motion of the bayonet and compressing the built-in spring. When the spring is fully compressed, the bayonet head is pulled through the contact, releasing the spring which gives a quick break to the bayonet contact. This quick break improves the performance of this contact in effecting final interruption of the circuit. It should be pointed out, however, that the quick-break action is not necessary from the standpoint of the production of overvoltages (see conclusion 4).

The rate of energy dissipation in the resistor is less during capacitor switching than it is during short-circuit switching, making the latter condition the necessary

* Voltage from capacitance potential divider.

criterion for design. The parameters for this situation are system voltage and value of resistance. For any given system voltage the energy dissipated in the resistor rises rapidly as the value of resistance is decreased. An 800-ohm resistor on a 138-kv system must be designed to handle 8 megawatts for the time it is required to be in the circuit.

This important factor of time that the resistor is in the circuit should include the time the resistor must carry current during both closing and opening strokes. Speed–time characteristics of circuit breakers generally are such that resistors are in the circuit an appreciably shorter time during closing than opening. This is fortunate, for if the circuit breaker is used for synchronizing, a closure between systems that are over 60 degrees out of phase increases the resistor current over the short-circuit values.

The resistors used on this project incorporate a factor of safety against burnout of from 2.5 to 3. The resistors are made up of Nichrome V wire, wound in helix, on grooved bakelite tubes, and the factors of safety were determined by actual performance of short sections of resistor helix observed under oil.

Figure 2 (above). Schematic diagram of 800–2,000-ohm step-type resistor circuit in 138-kv circuit breaker

Figure 3. One-line diagram of 138-kv and measuring circuits for switching tests

Description of Test Setup

A 1-line diagram showing the 138-kv circuits and the measuring circuits is given in Figure 3. Oscillographs were located at the terminal stations and arranged to be initiated simultaneously from either point. The experience with the failure of a lightning arrestor at Nichols Canyon junction between overhead and underground sections prompted installation of 500-ohm resistors and protective gaps set to break down at two times the normal voltage. Voltage measurements on the 138-kv buses were obtained through star-connected potential transformers at the terminal stations. *A*-phase-to-ground voltages on both ends of the circuit being switched were obtained through capacitance potential dividers made from the coupling capacitor potential devices that are installed permanently on the circuit. The capacitor stack of these devices consists of two 0.0033-microfarad capacitors in series. A 25-microfarad capacitor was substituted for the potential device and the voltage across this capacitor was used for the oscillograph. Because the ohmic value of the oscillograph circuit is in the order of 50 times that of the 25-microfarad capacitor at 60 cycles per second, such a

capacitance divider gives faithful reproduction of the 138-kv circuit voltage. By using capacitance potential dividers available on the line not being switched, comparison of *A*-phase system voltage as recorded by potential transformer and by capacitance divider was obtained. Comparison of these records shows that the potential transformer is satisfactory for recording system voltages at the frequencies encountered in these tests. Circuit currents were obtained from bushing current transformers in the circuit breakers used for switching.

Control of the circuit breaker under test was given the oscillograph and simultaneous operation of the oscillograph at the remote end was accomplished over an initiating circuit set up through communication cable between the two stations. Current in a tie-in circuit was recorded by both oscillographs so records from the two instruments could be identified in time.

Circuit Switching Tests Without Resistors

Thirty-one tests were made in which the Toluca-Fairfax West circuit was de-energized from receiving station *D*. Six of these tests were made with the 7-mile overhead line disconnected at Nichols Canyon. So far as could be determined, however there was no difference in performance with or without this 7-mile line section. The maximum overvoltage recorded on these tests was 1.82 times normal. This occurred on *A*-phase-to-ground system voltage in one of the early tests in which no measurements were made of voltage appearing on the circuit being dropped. In the 19 tests in which measurements of circuit voltage (*A*-phase only) were made, the maximum was 1.58 times normal. Complete data are presented in Table I.

Twenty-one tests were made in which the Toluca-Fairfax West circuit was de-energized from receiving station *E*. The maximum overvoltage recorded in these tests was 2.19 times normal. This occurred on the circuit voltage at the remote end; the corresponding circuit voltage at the end being switched was 2.11 times normal. The maximum system overvoltage recorded on these tests was 1.84 times normal and this occurred on the bus voltage at receiving station *D*; the corresponding bus voltage at receiving sta-

Circuit breaker without resistors

(A)

(B)

tion E, the point of origin of the transient, was 1.38 times normal. The higher voltage at the remote station is the result of rise caused by cable-charging current at transient frequency being drawn through the reactance of the 7-mile line (see conclusion 3). Figure 4 presents typical records obtained by de-energization from the receiving station E end. Complete data are presented in Table I.

These tests show that overvoltages from restriking are materially less when the circuit is de-energized from the receiving station D terminal. This arises because of the effect of the capacitance of the other cable circuit which remains connected to the receiving station D bus. The reason for the beneficial effect of capacitance on the system side of the circuit breaker is explained in reference 2.

Circuit Switching Tests With Resistors

The first tests were conducted using a single resistance of 2,000 ohms across the circuit breaker contacts. This gives an R/X_c ratio of 2 on a 5-mile cable and limits the overvoltages produced at the point of circuit interruption to 2.3 times normal in accordance with Figure 8. Amplification of transient overvoltages through system circuits makes a lower value of R/X_c desirable. The step-type resistor was developed next and tests were made using 720–2,000- and 600–2,000-ohm combinations.

The step-type resistor tests were made from the receiving station E terminal. They included four complete circuit de-energizations using the 720–2,000-ohm combination and ten interruptions with the 600–2,000-ohm resistor. The first auxiliary contacts which effect a change from the low to high value of resistance parted two cycles after the main circuit breaker contacts. The second auxiliary contacts which effect final interruption of the circuit parted five cycles later.

The maximum overvoltage recorded in these step-type resistor tests was 1.36 times normal. This occurred with the 720–2,000-ohm resistor and appeared on the bus at the remote station again emphasizing the importance of conclusion 3.

Figure 6. Oscillogram showing interruption of 80-ampere charging current by single-pole circuit breaker with 600–2,000-ohm resistors

Test producing no restrikes

The maximum appearing on the system at the point of circuit interruption was 1.13 times normal and the maximum on the circuit being interrupted was 1.15 times normal. Complete data appear in Table II.

Figure 5 presents typical oscillograms showing interruption of charging current with the circuit breaker equipped with 600–2,000-ohm resistors. These oscillograms show restriking on the main contacts with the attendant disturbance to voltage. They show restriking on the first auxiliary contacts which switch the circuit from 600 to 2,000 ohms, although this restriking produces no disturbance to system voltage. Some restriking occurs on the high-speed 2,000-ohm resistor contacts, but again this has no effect upon system voltage. Comparison of these oscillograms with Figure 4 brings out the beneficial effect of the step-type resistor.

The fact that no overvoltages resulted from restrikes on the contact interrupting the 2,000-ohm resistor current prompted tests to determine if the 2,000-ohm step could be eliminated. Tests were conducted on both the plain-break bayonet and the high-speed bayonet auxiliary contacts. Restriking occurred on both types of contacts and the arcing period was too long to be tolerated in normal operation of the circuit breaker. It was concluded that the step-type resistor is essential for satisfactory performance.

The tests showed that in spite of copious restriking on the contacts interrupting the 600-ohm resistor current, no overvoltage results from this restriking. The 600-ohm resistance gives an R/X_c ratio of 0.6 for a 5-mile cable circuit. It is quite likely, judging from these tests, that a considerably lower ratio of R/X_c must be reached before overvoltages will appear as a result of direct interruption of the resistor current (see conclusion 4).

Single-Phase Switching Tests

The normal speed of the crosshead in the circuit breakers on the Toluca-Fairfax circuits is 2.37 feet per second. To get an increased speed for test purposes, the full kicker-spring action was applied to one pole by disconnecting the remaining two poles from the circuit breaker control mechanism. This increased the crosshead speed to 5.3 feet per second.

Tests were conducted at receiving station D and the 600–2,000-ohm resistors were used. Single-pole operation enabled tests switching charging currents of 80, 160, and 240 amperes by using one phase of the cable circuit, then two and three phases, respectively, in parallel.

Six oscillograms covering the interruption of 80 amperes were taken, and restriking on the main circuit breaker contacts occurred on only two tests. Figures 6 and 7 show conditions with no restrikes and with restrikes respectively. Comparison of Figure 7 with Figure 5 shows the improvement gained by high contact speed.

Five oscillograms were taken interrupting 160-amperes charging current or the equivalent of ten miles of 138-kv cable circuit. With the 600-ohm resistor this is an R/X_c ratio of 1.2. A single restrike on the main contacts occurred on each of the five tests. Restriking occurred on all four tests made interrupting 240 amperes, which represents an R/X_c ratio of 1.8 or the equivalent of 15 miles of cable.

The tests with the single-pole circuit breaker demonstrate the improvement obtained by increasing contact speed. It is doubtful, however, if any great increase in speed is justified purely from a charging-current interruption standpoint as resistors, which have to be installed anyway because of the randomness of restriking, put a definite limit to the value of overvoltage produced.

This series of tests with the three values of charging current gives an empirical demonstration of the increase in overvoltages with increase in value of the ratio R/X_c. The maximum overvoltages obtained in the three cases were 1.04 times normal for 80 amperes ($R/X_c = 0.6$), 1.16 times normal for 160 amperes ($R/X_c = 1.2$), and 1.67 times normal for 240 amperes ($R/X_c = 1.8$). These actual values are appreciably lower than the theoretical values shown in Figure 8 partly because of the beneficial effect of the other cable circuit connected to the bus.

Short-Circuit Performance

This section of the paper discusses and reports the short-circuit performance of resistor-equipped circuit breakers. The application of resistors to a circuit breaker does not delay clearing system faults. It is true that the resistor delays actual disconnection of the circuit by several cycles, but the system is relieved of the fault just as quickly with the resistor-equipped circuit breaker as it is without resistors. The short-circuit performance of the main interrupting elements of the circuit breaker is in no way adversely affected by the use of the type of resistors described in this paper. However, outside of a tendency to force a more even voltage distribution over the interrupting ele-

ments of the circuit breaker, resistors have little beneficial effect on the interruption of fault currents.

Consider, for example, a short circuit on a 138-kv system involving a current of 8,000 amperes to be interrupted with a circuit breaker equipped with 800–2,000-ohm step-type resistors. The opening of the main circuit breaker contacts inserts the 800-ohm resistor in the circuit, and this resistor limits the current to 80,000/800 or 100 amperes. The resistor current is in phase with the voltage whereas the short-circuit current is lagging, making the difference current which the main contacts are required to interrupt still 8,000 amperes for all practical purposes. The duty on the main contacts, therefore, is unaffected by the presence of the resistor. Furthermore, the drain from the system is reduced from 8,000 to 100 amperes so the short-circuit disturbance is removed effectively from the power system by the operation of the main circuit breaker contacts. Final disconnection of the circuit does not take place until the 2,000-ohm resistor current of 40 amperes is interrupted by the second auxiliary contacts about four cycles later.

One pole of a circuit breaker equipped with 600–2,000-ohm resistors was subjected to actual short-circuit tests to demonstrate ability of the resistor to sustain this duty. The short-circuit tests consisted of five opening operations and four closing-opening operations. Oscillograms of the short-circuit tests showed satisfactory performance of the auxiliary contacts, and the resistor upon inspection gave no indication of excessive heat or deterioration.

Appendix. Protection Against Overvoltages Afforded By Resistors on Capacitor Switching

The insertion of resistance in series with the circuit as the main contacts of the circuit breaker part provides a path for discharge of the capacitor permitting decay of its voltage. Capacitor voltage thus tends to follow system voltage to an extent dependent upon the value of resistance, thereby reducing the value of the voltage across the circuit breaker contacts. This not only reduces the probability of restriking but reduces the value of overvoltages produced by restrikes when they do occur.

The protection afforded by resistors across circuit breaker contacts can be determined by an analysis of the circuit characteristics. This treatment of the situation uses the following symbols:

E_{m_s} = maximum instantaneous value of system voltage

e_s = instantaneous value of system voltage

R = ohmic value of resistance across circuit breaker contacts

C = farad value of line, cable, or capacitor

X_c = ohmic value of line, cable, or capacitive reactance

$\varphi = \tan^{-1} X_c/R$

E_{m_c} = maximum instantaneous value of voltage across X_c

e_c = instantaneous value of voltage across X_c

e_R = instantaneous value of voltage across R

$\epsilon = 2.71828$, the base of natural logarithms

t = time in seconds from instant R is effectively inserted in the circuit

E_{t1} = value of transient voltage on first restrike

E_{t2} = value of transient voltage on second restrike

E_{tc} = value of transient voltage on closing

The problem may be handled by expressing conditions of the circuit as the circuit breaker main contacts part to insert resistance in series with the line or cable X_c. Tests show that regardless of the point on the voltage cycle at which the high-voltage circuit-breaker contacts part, no significant change in current flow takes place until a zero value in the current cycle is reached. This makes it convenient to express system voltage by

$$e_s = E_{m_s} \cos \omega t \qquad (1)$$

as this expression has a value E_{m_s} when $t = 0$, the time at which the circuit change takes place.

At this time the instantaneous value of voltage across the capacitor must also be E_{m_s} but it immediately begins to change to a final value which may be expressed by

$$e_c = E_{m_c} \sin (\omega t + \varphi) \qquad (2)$$

In going from the one value to the other it passes through a transient state as the capacitor, which finds itself with more than enough voltage to satisfy the new steady-state conditions, begins to discharge through the resistance. The time constant of this transient discharge is determined by C and R. The complete expression for e_c is

$$e_c = E_{m_c} \sin (\omega t + \varphi) + (E_{m_s} - E_{m_c} \sin \varphi) \times \epsilon^{-t/RC} \qquad (3)$$

Equation 3 was demonstrated correct by oscillographic tests on miniature circuits in the laboratory.

The voltage which appears across the open contacts of the circuit breaker is the difference between e_s and e_c.

$$e_R = E_{m_s} \cos \omega t - E_{m_c} \sin (\omega t + \varphi) - (E_{m_s} - E_{m_c} \sin \varphi) \epsilon^{-t/RC} \qquad (4)$$

For the first restrike that might occur, the theoretical value reached by the transient voltage is the sum of the instantaneous value of system voltage and the voltage across the circuit breaker.[8]

$$E_{t1} = 2E_{m_s} \cos \omega t - E_{m_c} \sin (\omega t + \varphi) - (E_{m_s} - E_{m_c} \sin \varphi) \epsilon^{-t/RC} \qquad (5)$$

This expression may be simplified and brought to unit voltage basis by making $E_{m_s} = 1$ and expressing E_{m_s} in terms of E_{m_s} and the angle φ.

$$E_{t1} = 2 \cos \omega t - \sin \varphi \sin (\omega t + \varphi) - (\cos^2 \varphi) \epsilon^{-t/RC} \qquad (6)$$

Figure 7. Oscillogram showing interruption of 80-ampere charging current by single-pole circuit breaker with 600–2,000-ohm resistors

Test producing restrikes

Figure 8. Overvoltage protection obtained by resistors on capacitive switching

A—Overvoltage resulting from first restrike

B—Overvoltage resulting from second restrike

C—Overvoltage resulting from energization

D—Time that resistor should be in circuit on energization

The value of t for zero value of the differential of this equation establishes the maximum value of the transient overvoltage that occurs from a first restrike. Theoretically it can be argued that the most likely time for the restrike to occur is when the voltage across the circuit breaker contacts E_R is a maximum, but practically the "randomness" of the restriking performance may allow a restrike at some other time. It is believed, therefore, that the most pessimistic view should be taken for a design basis and the maximum E_{t1} should be determined irrespective of the voltage across the circuit breaker contacts. Actually for values of $R/X_c=2$ and above, the maximum value of E_{t1} occurs practically simultaneous with the maxium value of e_R but as the value of R/X_c de creases below 2 this is not the case. Field experience with a ratio of $R/X_c=0.6$ gave overvoltages, whereas no overvoltages should occur with this ratio under the premise that the circuit breaker does not restrike after e_R reaches its maximum. In this discussion, therefore, the pessimistic view is taken.

The differential of equation 6 is difficult to solve for t so the maximum values of E_{t1} were determined graphically for various values of φ. For this work it is convenient to express RC of equation 6 in terms of φ.

$$E_{t1}=2\cos\omega t-\sin\varphi\sin(\omega t+\varphi)-(\cos^2\varphi)\epsilon^{-2\pi\theta t\tan\varphi} \quad (7)$$

From the graphical determination of E_{t1} for various values of φ, the curve A of Figure 8 was plotted. This curve shows the theoretical maximum overvoltages that can occur as a result of one restrike for various values of R/X_c.

Curve B of Figure 8 shows the theoretical maximum overvoltages that can result from a second restrike. The curve is based, of course, upon the pessimistic point of view that the first restrike occurs at a time that gives maximum E_{t1} and further that the restriking arc is interrupted at the first current zero of this transient.

Curve B is based upon equation 8 which was developed by a process similar to that used to obtain equation 7.

$$E_{t2}=2\cos(\omega t+\theta)-\sin\varphi\sin(\omega t+\varphi+\theta)-[E_{t1}-\sin\varphi\sin(\varphi+\theta)]\epsilon^{-2\pi\theta t\tan\varphi} \quad (8)$$

The angle θ in this expression is $(180-\omega t)$ where t has the value which gave maximum overvoltage E_{t1} on the first restrike. It is determined graphically from equation 7.

The protection from overvoltages afforded by the resistor when energizing a capacitive circuit is of interest as a theoretical maximum of two times normal is possible without resistors. In order that minimum overvoltage be assured on energization the resistance must be in the circuit for a sufficient time to allow the energizing transient to die down to an insignificant value before the main contacts of the circuit breaker close.

The conventional time constant of a circuit represents the time required for the transient to decrease to 0.368 of its initial value. This is the value of ϵ^{-1} and is too high for the case at hand, so ϵ^{-4} was selected arbitrarily. This gives a factor of 0.02 for the initial transient which is negligible.

In the case of the capacitor-resistor circuit, the transient term is $\epsilon^{-t/RC}$ and the time t for the transient to decrease to 0.02 of its initial value may be obtained for any particular values of R and C by equating $-t/RC=4$. If t is expressed in cycles on a 60-cycle-per-second basis then

$$t=0.637R/X_c \text{ cycles} \quad (9)$$

Curve D of Figure 8 was plotted from this expression and shows the time in cycles that the resistance must be in the circuit on the closing operation if the overvoltages incident to closing the main circuit breaker contacts are to be limited to the values shown by curve C of the same figure.

Curve C was obtained from equation 6 after eliminating the transient term.

$$E_{t_c}=2\cos\omega t-\sin\varphi\sin(\omega t+\varphi) \quad (10)$$

This expression may be expanded and differented with respect to t.

$$E_{t_c}=2\cos\omega t-\sin\varphi\cos\varphi\sin\omega t-\sin^3\omega\cos\omega t$$

$$\frac{dE_{t_c}}{dt}=-2\sin\omega t-\sin\varphi\cos\varphi\times\cos\omega t+\sin^3\varphi\sin\omega t \quad (11)$$

The value of t at which E_{t_c} is a maximum is found by equating this differential to zero

$$\frac{\cos\omega t}{\sin\omega t}=\frac{\sin^3\varphi-2}{\sin\varphi\cos\varphi}$$

$$\cot\omega t=\frac{\sin^3\varphi}{\sin\varphi\cos\varphi}-\frac{2}{\frac{1}{2}\sin 2\varphi}$$

$$=\frac{\sin\varphi}{\cos\varphi}-\frac{4}{\sin 2\varphi}$$

$$\omega t=\cot^{-1}\left(\tan\varphi-\frac{4}{\sin 2\varphi}\right) \quad (12)$$

Equation 12 gives the values of t to substitute in equation 10 to obtain maximum values of E_{t_c} for various values of φ and as the angle φ is determined by R and C, this procedure gives data for curve C of Figure 8.

The curves of Figure 8 are convenient as they enable a quick determination of the theoretical limits to the maximum overvoltages obtained by using resistors in any particular application.

Discussion

W. F. Skeats (General Electric Company, Philadelphia, Pa.): In view of the advantages obtained by the use of resistors in circuit breakers particularly for the interruption of charging currents, when no single value of resistance gives the desired control, one naturally may consider a 2-step resistor. The authors of this paper have used such a resistor and have arranged to operate simultaneously two oscillographs a number of miles apart so as to get an indication of voltages at a point on the system other than that at which the breaker operation takes place.

These measurements have revealed the interesting fact that voltages at remote locations may be higher under some circumstances than at the point at which switching takes place. More surprising is the fact, not commented on by the authors, that these remote voltages were higher with both combinations of 2-step resistors than with the

Figure 1

ingle 2,000-ohm resistor. According to Table I, the maximum value for remote voltage was 1.22 with the single 2,000-ohm resistor against 1.36 and 1.25 with the 2-step resistors. It would be very interesting to know whether any explanation of this fact has occurred to the authors.

In attempting to analyze these tests, it also would be helpful to know what the connections were to the rest of the system.

E. W. Boehne (General Electric Company, Philadelphia, Pa.): The authors have presented an interesting paper on the art of interrupting leading current at high voltage. Field tests of the type presented are invaluable in evaluating the effectiveness of the various artifices of interruption. Their paper presents for the first time, data obtained on circuits whose capacitance consisted, in part, of cables. The oscillograms show that the high frequency current following a restrike has little tendency to interrupt following the first loop of high frequency current. This tendency is unusual from the writer's experience and prompts the question as to whether, in the opinion of the authors, this phenomenon is a characteristic of the cable circuits interrupted or a characteristic of the interrupter employed? In any event, it undoubtedly contributed to the low magnitude of surges obtained.

On the basis of lightning surges, arresters are initiated in the neighborhood of three times normal line to neutral crest. However, when the long flat-top voltages accompanying capacitor switching are encountered the lightning arrester initiates at a lower voltage which probably does not exceed 2.3 to 2.5 times normal. This trend is important to the protection engineer and further emphasizes the desirability of keeping high energy switching surges below twice normal voltage crest.

The characteristic of any interrupter unquestionably plays a part in the final determination of the means of accomplishing this goal. The authors are to be congratulated in achieving this result and presenting it in such an able manner. The low values of resistance used to accomplish their result are compatible with the exceedingly low opening speeds given in the paper. In other words, low opening speeds naturally require lower ohmic values of resistance to hold the voltage gradient to a safe level across the opening gap. It follows that much higher opening speeds will allow resistors of much larger ohmic value to produce the same voltage gradient across the opening break. The nominal tested ratio of ohms per pole to capacitive ohms to neutral of two is based upon an opening speed of from 6 to 7 feet per second on contact parting. It is reasonable to expect that this ratio will drop from 2 to 0.6 or 0.8 when the contact opening speed is between 2 and 3 feet per second.

These and other variations between various types of interrupters suggest that a satisfactory result, established by test, be sought for each style of interrupter and that no attempt be made to standardize upon a specific ohmic value of resistance for all field conditions. There is little doubt, however, that for a specific interrupter with a definite opening speed, that the true criterion of the resistance per pole is the capacitive ohms to neutral of the circuit.

Earl B. Rietz (General Electric Company, Philadelphia, Pa.): I believe that the authors should have restated in their introduction the obvious conclusion that the requirements for resistors arise only when there is restriking during capacitance current interruption. I mention this because there is a well-known type of oil breaker which from all the evidence available does not restrike and where one does not have to worry about overvoltages or resistor designs. This is the low oil content impulse breaker and 138-kv breakers of this type are operated by the Department of Water and Power of Los Angeles. Some of these breakers have been in service since 1934 and their excellent performance on capacitance current interruption is unquestioned. Figure 1 of this discussion shows a normal interruption of 200 miles of 230-kv line using the same type of breaker, and attention is called to the positive current clearing trace.

But, there were economic reasons which prevented the universal application of this type of breaker and it has been necessary to devise a means of limiting overvoltages on line switching for the tank type breaker designs. This problem came to a head in 1941 on the 230-kv Boulder Dam breakers and a description of the solution is included in the authors' references. A similar solution has been worked out for the 115- to 161-kv breakers. Therefore, for the past several years all General Electric breakers, 115 to

Table I. Capacitance Switching Tests on a Single 115–161-Kv Multibreak Interrupter With a 1,350-Ohm Resistor

996	44	138	0.1	0	2	None

230 kv, have been equipped so overvoltages from switching would be limited. It seemed impractical to study each application. Therefore, a more general approach was necessary and a resistor has been developed and co-ordinated with the interrupting characteristics of the multibreak interrupter so that the integral combination will give the desired results. This standard resistor not only had to limit the overvoltages on capacitance switching but had to have thermal characteristics suitable for instantaneous reclosing involving three applications of voltage within the relatively short period of 20 cycles. It was a further requirement that this resistor should not be a factor in determining tank size. In other words, it must not increase the over-all dimensions of the interrupter so that striking distances were reduced materially with a corresponding tank size increase. The manner in which this was accomplished was described before the Institute a year ago.[1]

The resistor-interrupter combination has been subjected to a number of factory switching tests. Cathode-ray oscillographs were used to measure the transient voltage conditions as it is considered that these give a much more accurate picture than the slower acting magnetic oscillographs.

Table I is a tabulation of tests made with 44 kv across a single interrupter equivalent to one-half of leg voltage at 154 kv. They are of interest because from a voltage and capacity standpoint, they represent a more severe condition than described by the authors where the charging current was only 80 amperes against the 130 amperes on these tests. There was no restriking recorded in the initial circuit interruption within the interrupter. Therefore, there were no overvoltages. Current transfer almost at the time of main contact separation illustrates the inherent ability of multibreak interrupters to interrupt light currents and avoid restriking. On one of these tests, there are two restrikes recorded before the interruption of resistor current. As the authors state, these have no significance. Figure 2 of this discussion shows the record of this operation.

These successful results on what can be considered a severe circuit indicate to us that the interruption of capacitance current is related to the type of interrupting device and its characteristics. The improved interruption under higher opening speed already had been mentioned by the authors. This is one of the desirable characteristics that the multibreak interrupter has. It works at a speed of 7 to 8 feet per second which automatically developed during the design tests to get $1^1/_2$-cycle arc duration even at light currents, a capacity of 3,500 millivolt-amperes, and a reclosing performance of less than 20 cycles. Those were the goals of "one breaker per voltage rating".

There is just one further thought regarding the use of the resistors for grading the voltage across the interrupting units of a pole. I think that this has come to be just as important a use for them as the one described in this paper. Minimum interrupting times demand that each interrupter be used to its fullest efficiency so that the voltage to be interrupted is shared equally. Why take longer times because of unequal distribution? Graded interrupters also seem to present the logical approach to supervoltages and superratings. Each unit can be tested more easily to capacity and when connected in series will give reasonable assurance of meeting rating.

Summarizing,

1. The oil impulse breaker has not evidenced any restriking on capacitance current interruption and therefore would represent the best answer for capacitance switching.

2. All General Electric high-voltage tank-type oil breakers are now furnished with interrupters and built-in resistors to avoid restriking.

3. The excellent performance of these modern breakers on line switching results from proper co-ordination of the interrupter and resistor designs.

4. Resistors also reduce interrupting times by grading the voltage across the interrupting elements which will aid materially in extending voltage and interrupting limits.

1. A NEW LINE OF HIGH-VOLTAGE OUTDOOR TANK-TYPE OIL CIRCUIT BREAKERS, W. F. Skeats, E. B. Rietz. AIEE TRANSACTIONS, volume 65, 1946, April section, pages 224–31.

R. C. Van Sickle (Westinghouse Electric Corporation, East Pittsburgh, Pa.): E. K. Sadler and T. M. Blakeslee have presented an important collection and study of data showing the effects of using resistors in circuit breakers to reduce the magnitude of transient switching overvoltages. Such data made during actual switching on systems, can be compared with calculated and theoretical values to validate the assumptions made in the calculations and the correctness or completeness of the theory.

As mentioned by the authors, the voltages obtained were less than the calculated maximums, the differences being caused in part by the presence of a parallel cable. I wish to emphasize these differences in test and calculated values.

In Figure 3 of this discussion are plotted the test values and the corresponding calculated curves of Figure 8 of the paper. The points represent the highest voltages reached for each condition. Because of the large number of tests which were made to determine these voltages, we have an additional strong confirmation of the argument that because of the modifying influences of breaker characteristics and circuit damping, the actual voltages reached while switching capacitive currents are much lower than predicted by calculations.

D. J. Marsden (Westinghouse Electric Corporation, San Francisco, Calif.): E. K. Sadler and T. M. Blakeslee are to be complimented for the paper just presented. The field test data relative to potential phenomena substantiates, at least qualitatively, the theoretical aspects of the problem, and are most interesting from the fundamental viewpoint. Inasmuch as electric circuits of this nature are difficult if not impossible to duplicate on a full scale basis in manufacturer's laboratories, it becomes essential to the industry that field tests such as these be made. This applies particularly in regard to tests such as those covered by this paper, as well as problems involved in switching long unfaulted high voltage transmission lines.

Resistors for voltage control have been applied to power circuit breakers for many years. The work covered by the paper just presented appears to be the first American application of the step type resistance principle to power circuit breakers of this rating.

In work of this character it should be kept in mind that the electrical and mechanical design of the resistor assembly must be considered very carefully in order to prevent the insertion into an otherwise fundamentally good design of a hazard even greater than that resulting from switching surges. This remark applies particularly in regard to shielding, increase in space requirements

and the associated reduction of electrical clearances, the mechanical complication of auxiliary "snap-action" contacts, and the relative location of the two resistor assemblies required in the step type design. Specifically in regard to the latter, following interruption of the current through the 600-ohm resistor, the bottom of this resistor assumes the same potential as the top, so that full potential appears between the bottom of the two parallel resistors, which appear from Figure 1 to be located quite close together. Furthermore, because of space requirements, it may prove quite difficult to apply this step type resistor to breakers included in the general design trend toward reduction of oil content of tank type oil circuit breakers.

Considering the 49 cable switching operations that were made without employing interrupter shunting resistors in which only one test indicated transient voltages more than two times normal and that equal to approximately 2.2 times normal, it becomes difficult to justify the increase in cost and complication of the step type resistor as compared with a single resistor unit of moderate ohmic value. Perhaps the authors would comment further on this point.

Complete information is not available in regard to the influence of low ohmic value resistors employed in circuit breakers applied to high speed reclosing duty. In asmuch as the mechanical problems relative to high speed breaker reclosing are being solved gradually, the speed at which the reclosing cycle may be adjusted is limited only by the deionization time of the temporary fault. Furthermore as the relay operating times and breaker interrupting times have been decreased to values of the order of 3 to 5 cycles, adding a deionization time of about 8 cycles of 138-kv service makes possible successful reclosing within only 12 cycles after the initial tripping impulse. However, if complete opening of the circuit is delayed several cycles by the use of resistors, the minimum reclosing time thereby is affected adversely.

In view of the excellent progress that has been made by design engineers in recent months toward improvement in the interrupting and charging current performance of oil circuit breakers it appears to me that we should guard against halting this development work by prematurely accepting the low ohmic value resistor as a total and complete solution to the charging current interrupting problem as contrasted with developments in design which offer comparably low switching surge overvoltages. Perhaps the low ohmic value resistors should be applied only in those instances where, either because of interrupter design or special circuit conditions, transient voltages as high as three times normal are likely to occur.

Figure 3

Figure 4. System connections for cable switching tests

E. K. Sadler and **T. M. Blakeslee:** In response to the suggestion of W. F. Skeats, Figure 4 is presented with this closing discussion to show the main connections for these cable-switching tests. In addition to the generating units shown there are a few small generating sources, both hydro and steam, which tie in to the receiving station 34.5-kv load networks. The number of generating units connected at the various times the tests were made was subject, of course, to the demands of the system at the time. The rated capacities of the synchronous units shown on the diagram are Boulder, 495 megavolt-amperes; San Francisquito plants, 129 megavolt-amperes; Seal Beach, 81 megavolt-amperes; Harbor, 81 megavolt-amperes; frequency changer at *RS-C*, 60 megavolt-amperes; synchronous condensers at *RS-B* and *RS-E*, 60 megavolt-amperes each; and synchronous condenser at *RS-A*, 30 megavolt-amperes.

The Boulder 287.5-kv transmission line sections are each approximately 90 miles in length. The 115-kv San Francisquito circuits are about 33 miles long, and the Seal-Beach 115-kv circuits are 24 miles long. The 115-kv lines between *RS-E* and *RS-A* are 11 miles long and those between *RS-A* and *RS-F* are 4.5 miles long. The 138-kv connections between *RS-E* and *RS-D* are described in the paper; the 138-kv lines between *RS-F* and *RS-B* are 8 miles long, those between *RS-B* and *RS-C* are 11 miles long, and the 138-kv cable connecting Harbor Steam with *RS-C* is 2.4 miles long.

Skeats points out that the maximum value of the voltage at the remote station was greater in the case of the step-type resistor than it was with the single 2,000-ohm resistor and he quotes values from Table II of the paper. This is explained by the fact that the single 2,000-ohm resistor switching tests were made at the receiving station *D* terminal of the circuit. When switching from this end there was no amplification of the transient system voltages. Indeed, the voltages at receiving station *E*, the remote station, were less than the corresponding system voltages at the point of circuit interruption. Furthermore, the magnitude of overvoltages produced by restrikes was limited by the presence of the other cable connected directly to the receiving station *D* bus. Switching from receiving station *E*, however, produced higher system voltages at receiving station *D*, the remote station, because, as stated in the paper, of a rise resulting from cable charging current at transient frequency being drawn through the reactance of the 7-mile line.

E. W. Boehne's question about the failure of the restriking current to interrupt at first current zero is an interesting point. It is primarily a characteristic of the cable circuits interrupted rather than of the interrupter. It will be observed from a study of Figure 4 of the paper, which shows an interruption from the receiving station *E* terminal, that the frequency of the restriking current is in the order of 740 cycles per

second, while the frequency superimposed upon system voltage is in the vicinity of 400–500 cycles per second. This was felt unusual and its explanation was suggested by Ray Witzke (Westinghouse Electric Corporation).

Referring to Figure 3 of the paper, the line and cable circuits viewed from the receiving station E 138-kv bus appear as shown by Figure 5 (presented with this discussion) if the cable sections are represented by their equivalent T circuits. The inductances L represent those of the 7-mile overhead sections. It will be observed from this figure that an inductance–capacitance circuit is formed. The calculated resonant frequency of this circuit is 715 cycles per second which is a good check with the 740 cycles per second actually recorded. It is apparent from the figure that the 138-kv bus voltage does not reflect this resonant frequency and therefore does not put zero voltage across the breaker contacts at the current-zero points of this frequency. This resonant frequency is superimposed, of course, upon the basic frequency of the restriking current which basic frequency is essentially the same as appears on the system voltage. While some of the restriking current pulses are extended, many of them are of short duration, indicating interruption at first current zero of the basic frequency, which is in line with the experience of Boehne.

The criticism of Earl B. Reitz is well taken, as overvoltages produced by capacitor-circuit interruption occur only when there is restriking. The impulse type of circuit breaker mentioned by Rietz was tested on the cable charging current and gave an excellent account of itself. The arc was cleared at first current zero following contact parting and no restrikes occurred. It is, however, obvious that a resistor-equipped breaker limits any overvoltages that may result from circuit energization, although resistors probably could not be justified on this count alone.

D. J. Marsden points out the necessity for careful design in any resistor installation having in mind such factors as shielding, reduction of electrical clearances, and the mechanical complication of auxiliary resistor contacts. There is no question that all of these factors must be considered carefully. In the particular case covered in the paper, shielding of the resistor tubes was not necessary because of the oversize tanks of the breakers involved. Generally speaking, however, shielding of the resistors is worthwhile in order to allow use of minimum tank diameter.

The auxiliary contacts used were necessary in this type of breaker because of the horizontal interrupting elements. While adding some complication they have the advantage that the time the resistor is in the circuit may be controlled easily by the simple adjustment of these contacts. The ability to cut down the time resistors are in the circuit to the minimum required to get the necessary protection from overvoltages gives a distinct advantage from the standpoint of factor of safety against burn-out. The use of the snap-action contact and the flexibility of contact adjustment resulted in an over-all time (dead-time basis) the resistors are in the circuit on a close-open operation of 3 cycles for the 800-ohm step and 5 cycles for the 2,000-ohm step. In contrast with this, for example, is the recent installation of resistors in the circuit breakers for the 230-kv lines of the Metropolitan Water District at Boulder. Although no auxiliary resistor contacts were necessary because of the vertical interrupting elements, the time of normal cross-head operation had to be accepted for switching the resistors in and out of the circuit. As a result the resistors are in the circuit on a close-open operation for an over-all time of 16 cycles. This means that either there is less factor of safety against burn-out or higher values of resistance must be used with a sacrifice in protection against over-voltages.

R. C. Van Sickle's discussion indicates some compunction about the use of resistors and Marsden finds it difficult to justify the increased cost and complication of resistors on the basis of the 49 tests made without resistors wherein only one test resulted in 2.2 times normal voltage. Of these 49 tests, 31 were de-energizations of the circuit from the receiving station D terminal, where the presence of the other cable limits the theoretical voltage build-up to 2 times normal instead of 3 times normal for one restrike. Switching from receiving station E is the most serious situation and the maximum of 2.2 was obtained out of 18 tests switching the circuit from this end. Also it will be recalled from the paper that a lightning arrester failed from overvoltage produced by switching out one of these circuits in normal operation. The failure of arresters is something that could not be tolerated. The manufacturer of the arresters stated that they could be expected to fail under these conditions, so it was apparent that something had to be done. As resistors offered a satisfactory solution, their installation certainly was justified.

As a further comment along this line, papers on switching charging currents have mentioned what has come to be known as

Figure 5. Equivalent diagram of line and cable circuits

"randomness of the restriking phenomena." The test work on the 138-kv cables definitely showed that restriking is a random thing. In addition to this, tests on a self-extinction principle circuit breaker without resistors at Boulder, interrupting charging current at 287.5-kv resulted in the discharge operation of a line lightning arrester once out of 21 tests. Subsequent records of normal operation of this line have disclosed another arrester discharge out of 21 line interruptions. An arrester discharge requires a voltage between 2.2 and 3 times normal and such discharges are likely to be damaging to the arresters.

Automatic reclosing is not in the situation covered by the paper. As Marsden points out, resistors delay the complete opening of the circuit by several cycles and therefore may adversely affect minimum reclosing time. In this connection the ability, previously mentioned in this discussion, of being able to adjust resistor time would offer considerable advantage. Where resistors have an adverse effect in fast reclosing applications, breakers that do not restrike on charging currents must be applied. The discussion by Rietz, however, indicates successful use of resistors in breakers for reclosing service.

As pointed out in the appendix of the paper, the application of resistors not only limits the overvoltages but also reduces the probability of the occurence of restrikes. Data presented in the paper indicate the advantages of high speed. The results of six tests by Rietz gave no restrikes, this performance being attributed to high speed and the use of resistors. Do these six tests guarantee that restrikes will never occur? Because resistors have to be used, it would seem prudent, in view of the random nature of restriking in a self-extinction principle circuit breaker, to use the value of resistance which establishes the desired limit to overvoltage, should restrikes occur. A guarantee of a definite overvoltage limit thus is obtained in any particular application.

Developments in Current Collectors for High-Speed Service

B. F. LANGER
NONMEMBER AIEE

THE CURRENT COLLECTORS used on most electrified railroads with overhead trolleys consist of diamond-shaped pantograph frames which support channel-shaped collectors, or shoes. Figure 1 shows a typical pantograph of the type used in high-speed main line service. The pantograph opens and closes to accommodate major changes in the height of the wire such as occur at bridges and tunnels. It is held up by means of springs. Special cams or linkages in the operating mechanism give the shoe a constant pressure against the wire for a range in height of several feet. Pantographs used in high-speed service also have secondary springs between the frame and the shoe in order to cushion the blows produced by sudden periodic or incidental irregularities, such as hard spots in the catenary. The pantograph of Figure 1 uses two shoes, each of which is supported by a pair of shoe levers, which are held up by spring action. The action of the shoe levers constitutes the secondary springing. The shoes are pivoted freely to the extremities of the shoe levers and thus can rotate about a horizontal axis perpendicular to the direction of motion.

A good current collector must not damage the trolley wire through heavy blows, excessive fatigue stresses, or excessive wear, and must have long shoe life. In order to have these qualities, the shoe must follow the wire smoothly at all speeds. The pantograph frames now in use have been found to operate satisfactorily at all operating speeds as far as following the major variations in wire height are concerned. At speeds above about 70 miles per hour, however, considerable difficulty has been encountered with the behavior of the shoes themselves and their secondary springs. Following are a few of the phenomena which have been observed:

1. At high speeds it is quite common to see a shoe flutter violently against the wire, which results in excessive arcing. Close examination of this flutter has shown that it is not a vibration of the shoe on its secondary springs, but a rotation about a horizontal axis perpendicular to the trolley wire.

2. It is difficult to obtain equal pressures on the two shoes of a double-shoe pantograph. In some of the mechanisms used, such as that of Figure 1, the wind force and wire friction tend to lift the leading shoe and depress the trailing shoe because of the arrangement of the supporting levers.

3. Secondary-spring systems which use pins and links have a tendency to bind and thus nullify the secondary springing.

The present paper describes some studies recently made by the Westinghouse Electric Corporation which have disclosed some of the causes of erratic operation and have resulted in a shoe and shoe mounting which give extremely smooth operation at the highest operating speeds. The engineers who co-operated in this development were H. C. Werner, formerly of the Westinghouse Research Laboratories; J. M. Robinson, section engineer in charge of pantographs and railway gearing; R. O. Heinemann, who designed the apparatus and conducted most of the tests; and the author.

Paper 47-8, recommended by the AIEE committee on land transportation for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted April 1, 1946; made available for printing October 29, 1946.

B. F. LANGER is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

The Collector Shoe as a Cam-Follower

The problem of making a correct collector follow irregularities in a wire at high speeds immediately suggests the similar problem of the cam follower. Suppose (see Figure 2) a follower of mass M is pressed against a cam by a spring of stiffness K with an average force P_0.

Let the shape of the cam be represented by the function

$$y = y_0 \cos \frac{2\pi x}{l}$$

The relative horizontal velocity between the cam and its follower is

$$V = x/t$$

If

$$\omega = (2\pi V)/l$$

the required motion of the follower is

$$y = y_0 \cos \omega t$$

The acceleration of the follower at any instant is

$$\frac{d^2y}{dt^2} = -y_0\omega^2 \cos \omega t$$

The spring force at any instant is

$$P_0 - y_0 K \cos \omega t$$

The pressure of the follower against the cam is

$$P_0 - y_0(K - M\omega^2) \cos \omega t$$

and this can be kept continuously positive by making P_0 sufficiently large. This means that the follower can be kept in continuous contact with the cam by making the spring setup force sufficiently large, no matter how soft the spring is. A soft spring is better than a stiff spring because it results in less fluctuation of contact pressure. A light follower is also advantageous. Damping in the spring is detrimental because part of the spring force must be used to overcome the damping force.

The essential difference between the

Figure 1. Typical pantograph for high-speed service

Figure 2. Cam-follower

Figure 3. Forces on collector shoe

cam follower and the pantograph shoe is that the pantograph shoe does not follow a fixed path. It pushes the trolley wire up between its supports and thus the amplitude of the oscillation is a function of the magnitude of the wire pressure. The exact solution of such a system involves considerable mathematical difficulty and has not been found necessary.

One phenomenon connected with this system which can be investigated easily, however, is the possibility of the collector shoe attaining a resonant velocity at which the lifting of the wire between supports would become excessively large. This velocity occurs when the speed of the collector equals the speed of propagation of a wave along the wire, and is

$$V = \sqrt{\frac{Tg}{w}}$$

where

V = speed in feet per second
T = wire tension in pounds
g = acceleration of gravity (32.2 feet per second^2)
w = weight of wire in pounds per foot

For a 0000 bronze wire under 4,000 pounds tension (the usual tension at 60 degrees Fahrenheit) this speed is 312 miles per hour. Thus the tension would have to be reduced to about one-tenth normal value to bring the resonant speed to 100 miles per hour.

The Collector Shoe as an Airfoil

When a collector shoe is carried along at high speed it is subjected to considerable wind force. In the conventional construction, a channel-shaped shoe is pivoted about a point below the wire (see Figure 3) and wind forces give it appreciable lift and drag. Because of wire friction, the shoe is tilted to an angle of attack between 0 and 10 degrees, which makes the lift larger than it would be if the contact surface remained horizontal. Wind tunnel tests were made on a conventional channel-shaped shoe with the results shown in Figure 4, curve *A*. The magnitude of the lift force was found to be sufficient to increase the wire pressure by over 100 per cent under operating conditions. This results in increased shoe and wire wear.

Various modifications of the shoe were tried, and the best practical construction was found to be a channel with a slot cut along the top and holes in the flanges. The lift coefficient for this shoe is shown in curve *B* of Figure 4. This shows a worth-while reduction in lift, but the wind tunnel tests disclosed another more important advantage which was entirely unexpected. The solid shoe had a strong tendency to flutter about its pivot support when held in the neighborhood of plus 5-degree angle of attack, whereas the shoe with the slots and holes was quite stable. The flutter observed in the wind tunnel was identical with the type of oscillation which has been observed in high-speed operation.

The flutter which occurs in channel-shaped shoes is an example of a self-induced oscillation. Its causes can be

Figure 4. Lift coefficients of standard (solid) shoe section and new section with cutouts

Figure 5. Air flow around collector shoe at various angles of attack

understood by reference to Figure 5. This shows the channel section in the wind stream at various points of the oscillation between 0 and 10 degrees angle of attack. In Figure 5*A* the shoe is horizontal but has started to rotate in a clockwise direction. In Figure 5*B*, it has rotated to an angle of 5 degrees. The flow follows the top surface of the channel because of the rounded corner. Like an airfoil with a positive angle of attack, the shoe has a lift force and an aerodynamic moment. The moment on the shoe is clockwise about the pivot support and aids the rotational velocity. In Figure 5*C*, the angle has increased to 10 degrees, at which point the flow can no longer follow the upper surface of the shoe. This results in a decrease of aerodynamic moment. At this point also, the wire pressure has built up to a sufficient value on the leading edge of the shoe to stop its clockwise rotation and start it back in the second half cycle of the oscillation. In Figure 5*D*, the shoe is passing again through the 5-degree angle, but in the opposite direction. If held in this position for any time, the flow over the top surface would re-establish itself as in Figure 5*B*, but this cannot happen instantaneously. Thus the aerodynamic moment (which now opposes the rotation) is smaller for the condition shown in Figure 5*D* than it was in Figure 5*B*. Therefore, over a complete cycle of the oscillation the aerodynamic moment has put energy into the oscillation because the moment which aids the oscillation is larger than the moment which opposes the oscillation. This results in net energy input and instability.

It can be shown that if the pivot support of the shoe is below the trolley wire, the wire friction also produces instability. The wire friction produces a clockwise moment about the pivot all through the complete cycle. Because of the different flow patterns, however, the aerodynamic lift is greater in Figure 5*B* than in Figure 5*D*. Therefore, the wire friction and the moment which it produces are greater during the half cycle when the moment aids rotation than they are during the half cycle when the moment opposes rotation. If the effective center of rotation of the shoe were above the trolley wire, the direction of the friction moment would be reversed, and the net result of friction would be to damp the oscillation.

The wind tunnel tests showed that the shoe with the slots and holes has not only a smaller lift coefficient than the solid section but also is aerodynamically stable. It is a poor airfoil but a good current collector.

Figure 6. Leaf-spring shoe mounting

Figure 7. Schematic view of leaf-spring shoe mounting

The Leaf-Spring Shoe Mounting

As a result of the foregoing studies, the shoe and shoe-mounting shown in Figure 6 were designed and built. The shoes contain the slots and holes which gave the lowest lift coefficient and the best stability in the wind tunnel tests. The secondary spring system contains no pins or levers, but is made up entirely of leaf springs. Figure 7 shows this spring system schematically, and Figure 6 in perspective view. Its action is based on the well-known principle that a body supported on two flat springs has an effective center of rotation at the point of intersection of the springs. The horizontal springs *A* and *A′* are parallel to each other and therefore give a vertical flexibility to the shoe without allowing any rotation. Therefore, wire friction and wind resistance do not lift the leading shoe and depress the trailing shoe, as occurs in the conventional shoe-lever mounting.

Rotational flexibility is obtained with the inclined springs *B* and *B′*. The extensions of the center lines of these springs intersect at a point above the wire. Therefore the center of rotation of the shoe is above the point of contact with the trolley wire, and the wire friction force results in stable instead of unstable motion, as previously explained.

Thus the design shown in Figure 6 has the following advantages over conventional constructions:

1. The shoes contain cutouts which give them low lift coefficient and aerodynamic stability.
2. The cutouts in the shoe allow the use of thicker material for equal weight, and thus give greater wearing depth and longer life.
3. The vertical flexibility is obtained with horizontal springs which act as parallel-motion devices. Therefore wire friction and wind resistance do not lift the leading shoe and depress the trailing shoe, as occurs in some double-shoe pantographs.
4. Elastic pivots have been used in place of the usual pin connections to the shoes. These improve the stability by placing the effective center of rotation above the trolley wire.
5. The new mounting contains no sliding surfaces so that all wear is eliminated except at the point of contact with the wire.
6. The springs are practically frictionless so that the full spring force is available for maintaining contact between the shoe and the wire.

A pantograph of the type shown in Figure 6 has been built and tried out in service. Observation at all speeds up to the highest commonly used showed that it justified all expectations. There was no evidence of shoe flutter at any speed, the only arcing being at switches and crossovers. In fact, the operation appeared to be affected only by the condition of the wire, and not at all by the speed. Further service experience is required to prove its mechanical adequacy, but it is believed that this model already has proved the correctness of the principles on which its design is based.

Discussion

R. L. Chapman (General Electric Company, Erie, Pa.): The developments of a pantograph design for high-speed service as described by Langer is quite interesting not only from the point of view that a needed improvement in existing equipment is possible but also in that it can be accomplished with a simplification in construction, including the elimination of wearing parts that previously have been considered essential.

I would like to ask if arcing can be minimized or largely eliminated by the use of the new type shoe with the otherwise old type of pivoted support; or, stated differently, can this development be divided into the following two parts?

1. Improvement in existing pantographs with respect to flutter, by the use of the new type shoe only.
2. Further improvement in over-all performance with decreased maintenance by use of the complete new development.

I feel that Langer and his associates are to be congratulated on a needed job well done.

B. F. Langer: We have not made sufficient tests to answer R. L. Chapman's question positively. We believe that the development can be divided into two parts, but prefer to reverse the order which Chapman suggests. In other words, it is believed that the change in shoe mounting is more important and more effective than the cutouts in the shoe itself. For most applications, the new mounting with the old shoe should be satisfactory. It is only for very high speeds that the aerodynamic force becomes large enough to justify the cutouts in the shoes.

At the present time, we are in production on 30 pantographs for moderate-speed service which have the leaf-spring mounting and solid channel-shaped shoes. Further high-speed tests on the original model are scheduled.

The Dielectric Properties of Cellulose Insulation Impregnated With Semiconducting Liquids

F. M. CLARK
ASSOCIATE AIEE

THE ideal and classical conception of a dielectric material includes the property of zero loss. Such an ideal material has not been realized but its conception has been the motivating influence which has prompted the continued search for dielectrics of the lowest possible loss characteristic. Conversely, it frequently is concluded that liquids of highly conducting characteristics are poorly suited for dielectric application.

Added emphasis is given to the arguments against the use of highly conducting liquids as impregnants of cellulosic electrical insulation by the dictates of experience. When an impregnated insulation fails under conditions of normal commercial usage, the failure invariably is proceeded by the chemical and dielectric deterioration of the insulation. This deterioration most frequently can be traced to changes in the liquid impregnant which are manifested inevitably in a lowered resistivity and increased dielectric loss. But this type of dielectric deterioration in an insulating liquid which is normally of low loss must not be accepted as indicative that all liquids having high loss properties are, ipso facto, of equal hazard. The factors which are involved in the chemical changes leading to higher loss in a liquid normally characterized by low loss usually present a hazard to continued dielectric use for reasons entirely aside from the loss characteristic itself. Mineral oil, for example, may deteriorate in commercial use and lose its initially low loss quality. The complete dielectric failure of the composite paper–oil insulation, however, is more likely caused by the loss of dielectric strength and the consequent formation of destructive corona at the normal voltage rating of the apparatus than to the increased conduction in the dielectric itself up to the point of accumulated heating. Deterioration products in oil which are responsible for this loss in dielectric strength and drop in corona formation voltage include the formation of gases, water, and low molecular weight acids.

The Normal Loss Level

Liquids suitable for the impregnation of cellulosic insulation have a "normal level" of resistivity or dielectric loss to which, in commercial use, they tend to revert from the more highly "refined" value obtained in the laboratory or factory. This "normal level" value varies widely with the chemical type of the liquid, being higher for the hydrocarbon compositions and lower for liquids composed of hydrocarbon substituents, such as the halogenated, nitrated, or esterified compounds. At its normal level of resistivity or dielectric loss, however, the dielectric strength of each class of liquids is high. In fact, because of a more equitable stress distribution, liquids of the lower resistivity or higher loss classification may possess even higher breakdown value than those of the lower loss hydrocarbon group. It is only when a liquid changes from its normal level of loss classification to one of higher loss that serious dielectric hazard is introduced. This hazard is usually traceable to the presence of contamination or products of deterioration which are reflected in an increased dielectric loss, but which to a greater degree affect the chemical stability of the insulation and lead to decreased ionization value and dielectric strength. The increase in dielectric loss, per se, is generally only of secondary importance. The case of mineral oil already referred to is an illustration of this type of hazard.

The object of the present paper is to illustrate the abnormalities which are met when cellulosic insulation is impregnated

Figure 1. The relation between the resistivity and 60-cycle power factor of a typical dielectric liquid

A 60-cycle power factor measured at 30 volts per mil
Resistivity measured at 500 volts direct current after one minute of electrification

Paper 47-9, recommended by the AIEE committee on electric machinery for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted September 10, 1946; made available for printing October 31, 1946.

F. M. CLARK is technical consultant on insulation and staff assistant to the manager of engineering, apparatus department, General Electric Company, Pittsfield, Mass.

Figure 2. The relation between the resistivity of the impregnating liquid and the power factor of the impregnated cellulose sheet

with high-loss liquids. These abnormalities are seized upon in the development of a new type of capacitor which is characterized by a high ratio of electrical capacitance per unit of physical volume. Such a capacitor offers promise of engineering application at voltages above those at which electrolytic capacitors can be used continuously with safety and below those at which the usual paper-spaced oil or askarel-treated capacitor can be used with economy. Such voltages include continuous alternating voltage application at 110 or 220 volts or intermittent voltage application up to and including 440 or 550 volts.

The Relation Between the Resistivity and Power Factor in Dielectric Liquids

Liquids may be classified on the basis of their resistivity as being of dielectric, semiconducting or conducting properties. The dielectric liquids may be classified as those which possess a resistivity greater than 1×10^9 ohm-centimeters. The semiconducting liquids are those having a resistivity lower than 1×10^9 but higher than 1×10^6 ohm-centimeters. Liquids having a resistivity lower than 1×10^6 ohm-centimeters are classed as conducting. The present paper deals primarily with the semiconducting liquids.

The resistivity or specific resistance of a dielectric liquid is the resistance in ohms of a quantity of the liquid one centimeter long and having a cross section of one square centimeter. The power factor is the cosine of the vectorial angle existing between the current and voltage applied to the insulation. It represents the ratio of the dissipated to the apparent power input in a circuit (watts/volt-amperes). In a circuit containing only resistance, the power factor is unity. In a dielectric, the power factor represents the total losses and varies with voltage, temperature, and frequency.

In Figure 1 is represented the normal relation between the 60-cycle power factor and the resistivity of a typical dielectric liquid.

In Figure 2 is illustrated the normally expected relation between the resistivity of the impregnating liquid and the power factor of the treated paper sheet.

The data of Figure 2 are confined to liquid resistivity values contained in the classification of "dielectric." It is this type of relationship which has warned investigators away from the consideration of liquids of even lower resistivity values (the semiconductors).

The Power Factor of Insulation as Related to the Resistivity of the Impregnant in the Semiconducting Range

Kraft paper, when impregnated with a semiconducting liquid having a resistivity in the range from 1×10^6 to 1×10^9 ohm-centimeters, shows marked abnormality in its dielectric power factor. From an extremely high power factor which is characteristic of kraft paper impregnated with a dielectric liquid having a resistivity of about 1×10^9 ohm-centimeters, the power factor of the treated insulation drops with the continued decrease in the impregnant resistivity below 1×10^9 ohm-centimeters. A minimum power factor of about three per cent is obtained when the kraft paper is impregnated with a liquid having a resistivity of about 0.01×10^9 ohm-centimeters (10×10^6). Further decrease in resistivity results in a rapid increase in the power factor of the treated insulation, a power factor of about 80 to 100 per cent being obtained when the impregnant resistivity is 0.001×10^9 (1×10^6) ohm-centimeters or lower.

Figure 3 illustrated the relation between the power factor of the impregnated kraft paper and the resistivity of the liquid impregnant in the semiconducting range (1×10^9 to 1×10^6 ohm-centimeters).

Figure 4 illustrates the power factor of kraft paper as a function of the resistivity of the liquid impregnant over the total

Figure 3. The power factor of impregnated kraft paper decreases as the resistivity of the impregnant is decreased through the semiconductor - classification range

range of dielectric and semiconducting classification. The abnormal power factor behavior in the semiconducting range of impregnant resistivity is illustrated clearly. It is this abnormality which is the subject of further analysis in subsequent paragraphs.

The Test Assembly for Cellulose Sheets Impregnated With Highly Conducting Liquids

Kraft paper impregnated with mineral oil or askarel is widely used as the solid dielectric in high voltage engineering practice. Treated with mineral oil, it is used as the insulation for high voltage cables. It is the most widely used spacer employed in capacitor manufacture. In this application it is commonly treated with askarel, the synthetic noninflammable type of impregnant.

In order to illustrate the dielectric behavior of kraft paper when impregnated with a liquid, it is most convenient to test the treated kraft paper in the form of a capacitor. For this purpose, typical capacitor windings were prepared. The dielectric consisted of two or three sheets of 0.0004-inch kraft paper which were wound between 0.0003-inch aluminum foil armatures. The capacitor windings were of sufficient length to give about $2^1/_2$ microfarads capacity when treated with mineral oil. The rolls were assembled in a standard terne plate capacitor case, the cover with its bushings was soldered in place, and the capacitor dried and impregnated through two holes arranged in the side near the top and bottom. After drying and impregnation these treating holes were soldered to give an hermetically-sealed container conveniently suitable for the detailed testing to which the dielectric was to be submitted. Figure 5 illustrates a typical test assembly.

Tricresyl Phosphate Compositions

Tricresyl phosphate is a liquid which lends itself satisfactorily to the study of the highly conducting liquids of the semiconducting classification. It possesses the following average properties:

Specific gravity (15.5 degrees centigrade compared with water at 15.5 degrees centigrade)	1.182
Saybolt universal viscosity (37.8 degrees centigrade)	107 seconds
Refractive index (25 degrees centigrade)	1.5550

Tricresyl phosphate is characterized by a normal level of resistivity of about 1×10^9 ohm-centimeters at 100 degrees centigrade. This classifies the liquid in the lower dielectric range or the upper range of the semiconducting grouping.

Figure 6. The resistivity of tricresyl phosphate–cresol compositions

When tricresyl phosphate is heated at temperatures above 100 degrees centigrade, it is pyrogenically decomposed with the formation of cresol or cresylic compounds. Such heat-treated compositions have reduced resistivities. Values as low as 1×10^8 ohm-centimeters are obtained when tricresyl phosphate is pyrogenically decomposed at 150 degrees centigrade. It is necessary in order to obtain resistivity values as low as 1×10^8 ohm-centimeters that the tricresyl phosphate be blended with a semiconducting liquid such as cresol. The resistivity of such blends is indicated in Figure 6.

The Power Factor of Kraft Paper Impregnated With Tricresyl Phosphate Compositions

The resistivity change illustrated in Figure 6 produced by the addition of the semiconducting cresol to tricresyl phosphate is reflected in an abnormality in the power factor of treated kraft paper. The power factor of the capacitor assembly described falls rapidly to a minimum of about 3.5 per cent when impregnated with a blend consisting of 20 to 30 per cent cresol in 80 to 70 per cent tricresyl phosphate. This is illustrated in Figure 7. The relationship between the resulting resistivity of the treating composition and the power factor of the treated paper is shown in Figure 8.

The minimum value observed in the power factor of kraft paper impregnated with the semiconducting compositions consisting of tricresyl phosphate and cresol is not peculiar to the cresol component. Using tricresyl phosphate as the solvent, the addition of a wide variety semiconducting solutes in order to decrease the resistivity of the impregnant produces similarly low power factor in the

Figure 5 (left)

Figure 7 (right). Showing the 60-cycle power factor of 0.0004-inch kraft capacitor paper as a function of the cresol content of the tricresyl phosphate impregnating composition

Figure 8. The 60-cycle power factor of capacitor kraft paper when impregnated with tricresyl phosphate compositions decreases to a minimum as the resistivity of the impregnant is decreased by the addition of cresol

treated kraft paper. Such semiconducting solutes comprise the phenols, the amines, the organic acids, and nitro compounds. However, the addition of water and alcohol compounds (glycerine, glycols, and so forth) or compounds having dielectric properties produces little decrease in the power factor of the impregnated kraft paper. The power factor of kraft paper impregnated with these compound blends is illustrated by the data of Figure 9. The relation existing between the power factor of the kraft paper and the resistivity of the impregnating composition is illustrated in Figure 10.

The Power Factor of Kraft Paper Impregnated With Compositions Not Including Tricresyl Phosphate

The decrease in the power factor of kraft paper impregnated with semiconducting liquids is independent of the use of tricresyl phosphate. The important factor producing this desirable result is the resistivity of the impregnating composition. As the resistivity of the semiconducting impregnant decreases from the upper limit 1×10^9 to its lower limit 1×10^6, the power factor of the impregnated kraft paper decreases steadily to a minimum which invariably, despite wide variations in the chemical composition of the impregnant, is obtained with a resistivity of the impregnant in the range from 1 to 20×10^6 ohm-centimeters. The minimum power factor obtained with the impregnated kraft paper, however, varies widely with the composition of the impregnant used.

The resistivity of a variety of impregnants as a function of the composition is illustrated in Figure 11. The power factor of the impregnated kraft paper as affected by the composition of the impregnant is illustrated in Figure 12. Figure 13 correlates the resistivity of the impregnating composition and the power factor of the treated kraft paper dielectric. The composition of the impregnants used and the impregnant resistivity corresponding to the lowest power factor obtained for the treated kraft paper in each case is summarized in Table I.

Figure 9. The power factor of the impregnated kraft paper is decreased by the addition of various types of semiconducting compounds to tricresyl phosphate used for the impregnation of the paper

Table I

Impregnant and Per-Cent Composition	Minimum Kraft Paper Power Factor, Per Cent	Resistivity of Impregnant at Lowest Kraft Paper Power Factor, Ohm-Centimeters
Cresol (47)–dibutyl phthalate (53)	4.7	4×10^6
Dibutyl tartrate (85)–dibutyl phthalate (15)	7.2	15×10^6
Cresol (11)–dibutyl tartrate (89)	4.5	20×10^6
Nitrobenzene (80)–cable oil (20)	5.1	2×10^6

The Effect of the Paper Spacer

The power factor characteristics described in the foregoing paragraphs for kraft paper impregnated with a semiconducting liquid are not characteristic of all insulations so treated but are markedly affected by the type of cellulosic sheet which is studied. Within the type classification of kraft paper, wide variations in the power factor of the treated sheet are produced as the result of physical changes in the sheet itself. In Figure 14 is illustrated the change in the power factor of the impregnated kraft paper which is associated with change in the density of the paper sheet.

More remarkable, however, is the effect produced by change in the chemical nature of the dielectric cellulosic sheet. Each type of paper, although subject to variation in power factor as the result of changes in the sheet itself (density and air resistance) has nevertheless a minimum power factor value which is characteristic of the paper used. As illustrated in Table II, among all of the sheet insulations tested, kraft paper sheets are characterized by the lowest power factor values.

Figure 10. Although the power factor of the impregnated kraft paper is decreased by the addition of a wide variety of semiconductor compounds to the tricresyl phosphate used for the impregnation, the minimum power factor obtained for the impregnated paper is affected by the type of semiconductor compound used

Equally interesting is the effect produced when a "mixed" dielectric pad is impregnated with a semiconducting liquid. Using a cresol tricresyl phosphate blend having a resistivity of 15×10^8 ohm-centimeters, capacitors containing alternate sheets of kraft paper and cotton or linen paper were prepared. By varying the number and thickness of the various sheets, the percentage of kraft paper has been varied over a wide range of dielectric composition. As the percentage of kraft paper present in the dielectric pad is increased in this manner, the high power-factor characteristic of the linen and cotton paper when used alone is reduced radically. Figure 15 illustrates the relation established. With dielectric pads consisting of 50 per cent or more of kraft paper, the power factor relation to the decreasing concentration of the second sheet is not affected by the chemical nature of the latter (cotton or linen).

The Capacitance Effect

It is an axiom that to obtain the lowest dielectric loss (power factor) in a heterogeneous dielectric such as an impregnated paper, a dielectric liquid of relatively low dielectric constant must be used. This results in part from purely electrical factors involving the molecular effects which accompany increase in the dielectric constant; but from a practical standpoint this results largely because of the greater solvent action increasingly possessed by liquids having dielectric constants of the higher magnitudes. Small increments in solvent contamination may seriously affect the initially high liquid resistivity with resultant increase in the power factor of the treated dielectric.

The high microfarad capacitance values obtained with cellulosic insulations impregnated with the semiconducting liquids belie the low dielectric constant characteristic of the individual component or components of the composite dielectric. Cellulose is attributed a dielectric constant value in the range from 5 to 7. Tricresyl phosphate has a dielectric constant of 7. The dielectric constant of ortho- and paracresol is about 6. Yet as the resistance of the liquid impregnant of kraft paper is decreased from 1×10^9 ohm-centimeters which is characteristic of tricresyl phosphate to a value in the range from 10 to 50×10^6, the capacitance increases to abnormally high values. The relation between the microfarad capacitance of such a capacitor and the resistance of the liquid impregnant (tricresyl phosphate-cresol blends) is illustrated in Figure 16. Figure 17 illustrates the increase in the capacitance of this same type of capacitor when the tricresyl phosphate "solvent" liquid is modified by the use of a wide variety of chemical types of semiconducting solutes. In similar manner the capacitance of dielectrics consisting of linen, cotton, or other cellulosic sheet materials is changed by the use of semiconducting impregnants.

An explanation of this abnormal capacitance behavior is obtained from a study of the effect produced when the clamping pressure applied to the dielectric is changed within wide limits, thereby changing the relative amounts of liquid and solid present in the dielectric pad, as well as changing the total distance between the electrode armatures. As is well known, in a truly dielectric pad, variations of this type are expected to be reflected in a changing electrical capacity of the dielectric assembly. When the cellulose sheet is impregnated with a semiconducting liquid having a resistivity in the range from 10 to 20×10^6 ohm-centimeters, substantially no change in the electrical capacity of the dielectric is observed. This is illustrated in Table III and in the data of Figure 18.

It is apparent that the physical changes introduced in the modifications of the dielectric described in Table III and in Figure 18 cannot involve any change in the dielectric constant of the assembly which would be of sufficient magnitude to explain the results obtained. The answer lies in the peculiarities of the semiconducting liquid. The true capacitance is determined solely by the thickness of the kraft paper dielectric used which is in all cases 0.0004 inch. Modifications in the total

Table II

Consistency of Impregnated Sheet	Range of Minimum Power Factor After Impregnation With Semiconducting Liquid, Per Cent
Linen paper	28–40
Cellate paper	16–23
Cotton	50–60
Cellophane	30–40
Creped kraft	25–35
Kraft	3–6

Table III

Dielectric	Total Dielectric Thickness Between Electrodes, In.	Electrical Capacity, μf
1 sheet 0.0004-inch kraft paper	0.0004	1.0
	0.00044	1.0
	0.0008	1.0
1 sheet of 0.0004-inch kraft paper in series with 1 sheet of:		
0.004-inch cheese cloth	0.0044	1.02
0.005-inch cheese cloth	0.0054	1.04
0.007-inch cheese cloth	0.0074	1.00
0.0075-inch cheese cloth	0.0079	0.98

distance between the electrode armatures is offset by the high conductivity of the liquid impregnant which in effect serves as a high-resistant conductor, thereby effectively bringing the electrode surfaces in close contact with the surface of the dielectric kraft paper sheet. Thus, although the apparent dielectric constant of the assembly is increased greatly by the modifications listed, the real dielectric constant remains unchanged, the abnormal capacitance increase being brought about by the introduction of a liquid electrode.

The Dielectric Strength

It has long been the desire of electrical manufacturers of low-voltage equipment to use a thin 1-sheet dielectric. This has been especially true in the manufacture of low-voltage capacitors rated for operation at voltages not exceeding 110 or 220 volts. The presence of conducting metal or carbon particles in the paper has prevented the practical application of such a 1-sheet dielectric. When tested over limited areas, one sheet of 0.0004-inch kraft capacitor paper after impregnation with mineral oil or similarly good dielectric liquid will give a breakdown in the range from 200 to 400 volts. When tested over a larger area, as in a capacitor, such insulation invariably shows little or no insulating value, because of short circuits produced between the electrodes as a result of the presence of conducting particles. The same insulation (0.0004-inch kraft paper) when impregnated with a semiconducting liquid and assembled in a loose form, as for example, with a total distance between the electrodes about 50 to 100 per cent greater than the paper thickness itself will show the dielectric strength characteristic of the small area tests as normally carried out in the laboratory examination of oil or Pyranol*-treated paper. This is illustrated in the data of Figure 19. At room temperature (25 degrees centigrade), the dielectric

Figure 14. The power factor of kraft paper when impregnated with a cresol–tricresyl phosphate blend having a resistivity of 20 × 10^6 ohm-centimeters is greatly affected by changes in the density of the paper sheet

Figure 15. The power factor of the impregnated cellulosic insulating pad impregnated with a semiconductor composition is a function of the amount of kraft paper contained in its assembly

strength of the 0.0004-inch kraft paper therein illustrated is 360 volts (900 volts per mil). This ability of the one sheet of 0.0004-inch kraft paper dielectric to resist breakdown when impregnated with a semiconducting liquid is associated with the ability of the liquid to act as a liquid conductor while at the same time manifesting a dielectric strength of about 150 to 200 volts per mil under the usual test conditions. The effect of the conducting particles in the paper sheet thereby is masked effectively.

The Permalytic Capacitor

In the industrial application of capacitors, two requirements are inevitably imposed. The capacitor dielectric must be electrically stable and the capacitor must occupy the smallest possible physical space per microfarad of capacitance. Dielectric stability is paramount because of the severe conditions of electric stress and temperature to which the capacitor may be exposed in normal service.

In the manufacture of capacitors, Pyranol and similar impregnants of the askarel type possess advantage. The dielectric constant of these impregnants is about five. Their use gives the smallest physical capacitor volume per microfarad of any liquid impregnant heretofore used commercially in the manufacture of paper-spaced capacitors. However, even the application of this type of capacitor at voltages in the range of 110 to 220 volts gives relatively large physical volume per microfarad. The physical volumes per microfarad for typical capacitors of this type are given in the following tabulation

2,400-v rating	41.3 cubic in. per kva
360-v rating	58.4 cubic in. per kva
230-v rating	117.0 cubic in. per kva

The large physical volume per kilovolt-ampere of electrical capacity is caused principally by the limitations imposed by the paper spacer. It has been found on the basis of experience that the use of a laminated dielectric composed of less than three sheets of capacitor paper introduces a manufacturing hazard because of the presence of conducting particles in the paper sheet which greatly affect the dielectric strength. Nevertheless, even a 2-sheet dielectric of the thinnest type gives a capacitor of large bulk. A capacitor containing two sheets of 0.0003-inch capacitor paper when operated at 230 volts, operates at a stress of 383 volts per mil. Such a capacitor occupies a physical volume of 45.5 cubic inches per kilovolt-ampere. When operating at 110 volts the dielectric stress is only 183 volts per mil. At 110 volts, such a capacitor occupies a space of 182 cubic inches per kilovolt-ampere. Such applications are uneconomical and are usually objectionable because of space limitations. The Permalytic capacitor, based on the behavior described for the semiconducting impregnated paper spacer, presents an economical solution to the problem presented. The Permalytic capacitor is defined as a kraft paper spaced capacitor of the usual type, the impregnant of which consists of a semiconducting liquid.

The Permalytic capacitor is characterized by a physical volume equal to about 40 per cent of that of the askarel type of capacitor and about 30 per cent of the

physical volume of the oil or wax impregnated capacitor per kilovolt-ampere. Figures 20 and 21 illustrate the relative sizes of typical low voltage mineral-oil Pyranol and Permalytic types of capacitors.

The Permalytic capacitor operates with a power factor of about three per cent. It is adapted technically and economically for use at continuous voltages up to approximately 220 volts and for intermittently applied voltages as high as 440 or 550 volts, applications where the dielectric type of capacitor is economically handicapped in its operation. Because of its small size and relatively high power factor, the problems of heat dissipation in operation react against the use of the Permalytic capacitor on continuous voltages higher than about 220 volts.

The power factor of the Permalytic capacitor is substantially constant over the usual temperature range from 25 to 75 degrees centigrade. This is illustrated in the data of Figure 22. The 25-degree-centigrade power factor of 3.5 per cent is not exceeded by increase in temperature up to 100 degrees centigrade.

The electrical characteristics of the Permalytic capacitor are stable during operation on continuously applied voltages. This is illustrated in the data of Figure 23 which describes the behavior of a 1-kva 110-volt capacitor operating in an ambient temperature of 70 degrees centigrade. In Figure 24 the power factor and capacity stability of a 165-volt 20-microfarad capacitor is illustrated.

In Figure 25 is illustrated the capacitance and power factor stability of the Permalytic capacitor rated at 440 volts on intermittent voltage duty, 440 volts being applied $1^1/_2$ seconds in each minute. Figure 26 illustrates the dielectric stability of the Permalytic capacitor rated at 250 volts, the voltage being applied for $1^1/_2$ seconds in each minute.

In view of the characteristics which have been described, the Permalytic capacitor offers interesting possibilities for those applications where a small dependable low-cost low-voltage capacitor is required.

Discussion

T. W. Dakin (nonmember; Westinghouse Research Laboratories, East Pittsburgh, Pa.): F. M. Clark's paper has demonstrated experimentally a very interesting phenomenon that may occur in heterogeneous dielectrics. The power factor maximum shown in Figure 4 of the paper, which results when the resistivity of an impregnant is decreased, has been observed before. An analysis of an equivalent circuit for the

Figure 1A

Figure 1B

Figure 2A

Figure 2B

system, where an essentially loss-free capacitance is placed in series with a second capacitance which is in parallel with a resistance, as in Figure 1A of this discussion, will show that the dissipation factor of such a combination will increase and pass over a maximum as the resistance is decreased, as in Figure 1B. The analogy of this circuit with the impregnated paper is obvious. The capacitance C_1 and resistance R_1 represent the impregnant, and the capacitance C_2, the solid paper fiber, the power factor of which is neglected.

Clark's data show that a minimum occurs as the resistance is decreased still further. This could occur if there is a resistance leakage path around the paper fibers. This resistance, therefore, should be much higher than the equivalent resistance of the impregnant R_1 shown in Figure 1A of this discussion, but should be proportional to it. Let it be designated as KR_1, where K is a proportionality constant greater than unity. This resistance would appear in parallel with the paper fiber capacitance C_2, Figure 1A of this discussion. Our new equivalent circuit then is as shown in Figure 2A. An analysis of this circuit shows that its dissipation factor has both a maximum and a minimum as in Figure 2B like those demonstrated experimentally by Clark. The expression for the dissipation factor of equivalent circuit in Figure 2A is

$$\frac{(1+K)+W^2R_1^2K(C_1^2+KC_2^2)}{WR_1(C_1+K^2C_2+W^2R_1^2K^2(C_1C_2^2+C_2C_1^2))}=\tan\delta$$

where

$W=2\pi f$

Sample calculations using reasonable values for C_1 and C_2 have shown that the proportionality constant K should be about 50 to 100 to get the proper separation of minimum from maximum shown by Clark's data. It is assumed that C_1 and C_2 are of the same order of magnitude, and, for purposes of calculation, they are taken equal to the dielectric constant times the capacitance of a centimeter cube in vacuum. This is consistent with resistance in ohm-centimeters. This calculation shows that the minimum occurs at a resistivity of impregnant of about 10^9 ohm-centimeters, which is in reasonably close agreement with Clark's data considering the crudeness of the assumptions made in the calculation.

A more careful examination of the analogy between the equivalent circuit and the actual dielectric situation may lead to a still better agreement with the experimental results. No account was taken in these calculations of the distribution of space in the over-all dielectric between the paper fiber and the impregnant; it merely being assumed that there was an equal and uniform mixture of liquid impregnant and solid paper fiber.

This equivalent circuit analogy gives an explanation of why Clark obtained a surprisingly low power factor with a rather low resistivity liquid impregnant in paper. The equivalent circuit analogy for the explanation of the behavior of composite insulation was used by H. H. Race,[1] and the present discussion extends the analogy to the special conditions existing in Clark's experiments.

1. Capacitance and Loss Variations with Frequency and Temperature in Composite Insulation, Hubert H. Race. AIEE Transactions, volume 52, 1933, pages 682–92.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): The author is to be commended for doing the unexpected in developing a suitable dielectric using semiconducting liquids. It would be of interest to know the specific inductive capacity for these capacitors.

According to the paper, the capacitors consist of only one layer of paper but the clamping is so loose that the liquid film layer is at least equal to the paper thickness. By this method, it is indicated that the breakdown of weak spots in the paper is avoided. This raises the question as to whether the liquid film separation can be maintained indefinitely, especially in curved portions of the wrappings.

F. M. Clark: T. W. Dakin's analysis is of interest. In accordance with this analysis, leakage measurements over the surface of the various types of paper fibers may lead to an explanation of the power factor values obtained as the composition of the spacer is changed. Although not clearly indicated in the paper, semiconductor impregnants which attack the spacer fiber (pulp) invariably give high power factor for the impregnated sheet. Furthermore, improperly dried cellulose spacers yield higher than the normally expected power factor. These facts appear to be in accord with Dakin's analysis.

The specific inductive capacity of the various semiconducting liquids varies widely with their composition. Tricresyl phosphate has a specific inductive capacity of about 7. Most of the compound blends have a specific inductive capacity in the range from 6 to 14. Despite this wide range of the specific inductive capacity of the liquid, the final capacitance of the capacitor for a given condition can be predicted merely from calculations based on the characteristic of the treated paper without reference to the thickness of the liquid film (tightness of clamping).

Experience has shown that the effect of weak spots in the paper layer are eliminated effectively by insuring the presence of a thick layer of the semiconducting liquid as is obtained by having a loosely clamped structure or its equivalent. Dielectric failure on life test rarely, if ever, has been traced to the presence of conducting particles in the paper sheet.

A Study of the Relative Severity of Steep Front Waves and Chopped Waves on Transformers

F. J. VOGEL
MEMBER AIEE

THE USE of reinforced turn-to-turn insulation on the line coils of transformers is nearly as old as the art. The amount used was a matter of individual belief and custom on the part of the designer. The same is essentially true of the insulation between coils. In the effort to remove empirical practices and place design work on a sounder basis, it was found necessary to find means of evaluating the dielectric strength of line coil assemblies as well as to find the actual voltage stresses which existed. It usually is thought that the dielectric strength of assemblies under oil is purely a question of the separation and the materials. One direct result of this latter reasoning is the belief that if a given voltage stress is obtained between the line coils of a transformer, it is immaterial whether it is the result of a sudden voltage rise as from a steep front wave, or the sudden voltage drop obtained by a gap flashover.

It is the purpose of this paper to show why the actual strength between coils cannot be estimated so easily, and why the strength between coils is not the same with voltage rise or fall.

More specifically, a typical arrangement of transformer winding is studied to determine its dielectric strength near the line terminals under impulse conditions. It is then apparent that it is difficult to estimate the strength of such assemblies and that an approximate method for estimating the strength is required. The shape of the dielectric field for both steep rise and steep collapse of voltage is shown, and the relative stress in both cases is estimated. These show that the steep rise is generally much more to be feared and that special precautions, shielding, or special winding arrangements are necessary.

Paper 47-16, recommended by the AIEE committee on electric machinery for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted October 11, 1946; made available for printing November 13, 1946.

F. J. VOGEL is a professor in the department of electrical engineering, Illinois Institute of Technology, Chicago, Ill.

General Voltage Stress Considerations

A representative transformer is shown on Figure 1. The dielectric field between the line and second coil is to be studied, and Figure 2 shows a section of these coils, taken from the area outlined by dotted lines in Figure 1. Let us first assume that the winding is uniformly spaced. The voltage distribution of such a winding is shown on Figure 3 for a steep front wave. Figure 4 shows the dielectric field which would be obtained with the coil arrangement in Figure 2, but with an applied 60-cycle test to the whole winding. Figure 5 shows the dielectric field obtained with the voltage distribution shown in Figure 3.

Figure 5 shows clearly that the dielectric strength between the two first coils is affected by the presence of the whole dielectric field. The highest stresses are at the points A and B. If the insulation at both places is the same or in proportion to the stresses immediately at the corners, failure along the columns of coils starting at B will be no more likely under surge conditions than failure from the upper corner of the static plate to ground. However, it also will be seen that the distribution of stress in the dielectric at the upper corner of the static plate to ground may be different in the cases of Figures 4 and 5. This in turn means that the dielectric strength is not the same under both conditions. Shielding, by placing line potential at the outside of the second coil, could make the dielectric field in the major insulation approach the same shape under 60-cycle and impulse conditions, at the expense of insulating between the shield and the coil. This case is not considered here because it is not used universally and is not the general case.

When a transformer has had a surge applied to it, the surge appears to travel along its winding as shown in Figure 6, taken from a recent AIEE paper.[1] This is representative of transformer windings without excessive end turn insulation and coil spacing and is referred to for this reason. It would be possible to have a gap flashover with a relatively steep collapse of voltage, when coils 1 to 4 were at about the same potential. Figure 7 shows how different the field conditions are when the voltage and dielectric field collapse than when it is applied. The maximum voltage stress is at C instead of A and is of lower magnitude even though the stress between coils is the same, because the voltage to ground is so much less.

Comparison of Stresses, Initial Distribution of Entering Wave, or Chopped Waves

In a previous paper, the effect of the entering wave, provided it is of steep front, was discussed.[2] A typical insulation arrangement was shown similar to Figure 2 in this paper and Figure 4 in the previous paper. For this condition a specific example, that of a 138-kv transformer, was taken and it was shown that it could have a full wave surge strength

Figure 1. Typical arrangement of core and coils in circular coil transformer

of 760 kv based on a 275-kv 60-cycle test with a major stress at A or B. However, if the voltage surge were to collapse suddenly, it is seen that the maximum stress would be no longer at A or B but at C. From Figure 7, it is also seen that conditions are much better than they previously were because the gradient at C is much less after flashover than it was initially at B, as shown in Figure 5. B is now at ground potential and C only at 50 per cent of the surge voltage at the line at the time it was chopped. If C were equally as well-insulated as B, and the proportions were as shown in Figure 8 of this paper and Figure 6 of the former paper, the total voltage at C could be 63

Figure 2. Section of line coils and static plate in dotted section of Figure 1

Figure 3. Typical voltage distribution of steep front surge α = 14, 40 coils, with no voltage penetration

This is case where there is a large number of turns in the line coils

per cent of that originally from A to G. If the original surge strength at A was 820 kv, the dielectric strength from C to B should then be 518 kv. If because of distribution, the voltage at C is only 50 per cent of the original surge, it would be only 380 kv or less. Without going into further detail, it is seen that the conditions are vastly different. In fact I believe that because of distribution of stress, many transformers have been built with point C insulated for about two-thirds of the strength of B, and have withstood both impulse tests of the American Standards Association type and steep fronts in the order of those stated in the previous paper.[9] Another way of saying this is to state that the voltage stress at C for the chopped wave, as compared to that at B on initial distribution, is only about 65 per cent. In a recent discussion,[8] kilovolt values of 412 for chopped waves and 347 for steep front waves were quoted for stresses between coils with 2-per-cent turns. If the 412 kv were derated on the aforementioned basis of severity, it would become equivalent to 412×0.65 or 267 kv as compared to 347 kv for the steep front, although this is still not quite a true picture of the actual comparative strengths because time factors are not considered.

Besides the coil edges, the flat area between the coils and the turn-to-turn insulation is stressed. The field between flat coil surfaces is obviously less concentrated than at the coil corners, and failure at the corners would be expected unless faulty oil impregnation or material were obtained. Likewise, core type transformers seldom have more than 50 volts per turn based on their normal 60-cycle rating. If so, a similar transformer to the one just discussed would have not over 2,760 total turns. Two per cent would be 55 turns. If the turn-to-turn stress were distributed fairly evenly, we

Figure 4. Approximate field plot of dielectric field adjacent to section shown in Figure 2 during 60-cycle test

Figure 5. Approximate field plot of dielectric field under impulse conditions as shown in Figure 3

Figure 6. Variation of stresses in core type transformer with time, taken from Figure 4 of reference 1

It is seen that a large part of the line coils are at the same voltage after 18 microseconds

Figure 7. Approximate field plot of dielectric field under impulse conditions at time of chopping surge

would have 412/55 or less than 8 kv per turn. Very little turn-to-turn insulation would be required to stand that stress, indicating clearly that the use of excessive turn-to-turn insulation is not warranted, as the dangerous stress is at the coil corners. Even with considerably less turns and allowing for some variation from uniform stress, the turn-to-turn stresses are low and not a likely cause of failure for this type of transformer. Even today many engineers believe that extra turn-to-turn insulation on the line coils is desirable, and text books state that it is required seemingly on an empirical basis. Actually, its use is undesirable in many cases.

Conclusion

The results of this study show that the steep change in voltage caused by surge flashover does not stress the insulation between coils in a core type transformer in the same manner, nor nearly as severely as a steep front surge. The important parts of the line coil insulation are the corners of the inner and outer diameters of the coils, and not the flat area nor the turn-to-turn insulation in most cases. The value of methods of evaluating the strength of the insulation at the corners of the coils under various stress conditions as described in the previous paper[2] is shown. The need of supplying special insulation at these corners, or of shielding is apparent. If steep front waves are obtained in practice, the use of such waves would be recommended for test in place of the present chopped waves

Discussion

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The meat of Professor Vogel's paper seems to be in the first paragraph under "Comparison of Stresses, Initial Distribution of Entering Wave, or Chopped Waves." Unfortunately however, the use of numerical values for several different coil stacks is confusing and the proof of his statements cannot be verified.

It is possible that Professor Vogel intends to point out that for the steep-front chopped waves, the relative stress between coils is greater than for the standard chopped waves because of the simultaneous existence of high coil-to-coil and high coil-to-ground stresses. (Figure 5 of paper). The coil-to-ground stresses then may initiate a breakdown of the insulation to ground at B, which, in turn, might result in a coil-to-coil failure from B to C because of the high stresses existing between these two points. For chopped waves (Figure 7 of paper) the situation is considerably more favorable in his opinion, because at the time of high coil-to-coil stress from B to C, point B is at ground potential and the failure cannot be initiated at that point.

However, such an analysis neglects the facts that

1. Coil-to-coil stresses may be higher than those obtained by the initial distribution of Figure 3 of the paper at times other than those accounting for the initial distribution.

2. Stresses to ground are produced at points B and C by the chopped wave previous to the chopping.

Professor Vogel, in reference 2 of his paper, assumes a ratio of crest voltage of a steep-front wave chopped at 1 μs to a chopped wave chopped at 3 μs of 1.25. This implies that the strength of the insulation to ground at B is then equivalent for a steep front chopped wave and for a wave chopped at 3 μs, respectively. Therefore, if the insulation to ground is insufficient for one, it will fail also on application of the other type of wave.

Highest coil-to-coil stresses are not necessarily coincident with the initial distribution. They may occur either before or after the crest of the applied wave is reached. Figure 1 shows how coil-to-coil stresses on the front of the chopped wave reach their maximum peak before crest is reached, while after the chop, maximum stress of opposite polarity is obtained approximately 0.3 μs after the applied wave has decayed to zero.

I believe the fundamental difficulty in arriving at definite conclusions lies in the fact that the relative severity of the two types of waves varies greatly with different types of transformers and depends principally on the following factors: natural

Figure 1. Voltage transient between coils in a transformer winding when a 1.5x40μs wave chopped at 5μs is applied

Tap *a*—3.8 per cent from line end of winding

Tap *b*—7.4 per cent from line end of winding

frequency of oscillation, turn density per inch length of winding, degree of shielding, shape of the applied wave and the volt-time curve of the insulation and electrode assembly.

In general, the relative severity will vary from one transformer to another, and it is impossible to promulgate general conclusions as Professor Vogel attempts to do.

Several papers[1,2,3] have been written in the past few years which show that the bus voltages in stations protected by lightning arresters are held well below the full wave test levels of the transformers in the stations investigated. Judging from the data collected in such field investigations, and based on service experience and service requirements, a thorough study of the insulation test levels might prove valuable.

J. R. Meador (General Electric Company, Pittsfield, Mass.): F. J. Vogel has presented an interesting discussion of the dielectric field at the line end of a small unshielded core-type transformer. It is obvious, as pointed out by Vogel, that the dielectric field at the edge of a coil depends not only on the voltage to the adjacent coil but also on the location of ground. Numerical values are used to illustrate the method of attacking the problem. The values used, however, appear to be taken from such unrelated sources that the general conclusions are questionable.

The original assumptions are that the winding is uniformly spaced (that is, turns per coil and coil ducts are the same in the body of the winding as at the ends) and has the proportions shown in Figure 2 of the paper. For such a winding the impulse voltage distribution in Figure 3 and the field plots in Figure 4 and Figure 5 are undoubtedly correct. The field plots show the spacing between coils to be one-half the spacing to ground. Surely this is not representative of a 138-kv winding. Such a space factor does not appear to be practical, even for a high voltage unshielded winding. If the proportions are not representative, then the conclusions regarding the voltage stresses at the coil edges have limited validity. Also, there is no reason to believe that the voltages across two per cent of winding given in reference 3 were from a transformer whose proportions were similar to those in the field plots.

The rather broad conclusions concerning turn insulation also appear to be drawn from meager data. Taking Vogel's assumptions and applying them to a large transformer, some radically different conclusions can be drawn. Assume a Y-connected, unshielded 132-kv transformer with 200 volts per turn rather than 50, and 60 coils instead of 40. With winding uniformly spaced, the turns per coil is between six and seven.

In an unshielded winding of this sort the static plate has little effect on the impulse voltage distribution, except across the line coil. The voltage distribution is, however, sensitive to rate of change of voltage. In fact, for very steep waves, the turn to turn voltages near the line end are, in a rough way, proportional to the rate of change of voltage. On the American Standards Association chopped wave the voltage drops from 750 kv to essentially zero in 0.05 to 0.2 microsecond. Taking an average value of 0.1 microsecond, the average rate of change of voltage is 7500 kv per microsecond. Contrast this with the usual steep wave test which rises at 1000 kv per microsecond. The turn to turn voltages on the chopped tail actually will not be 7.5 times as much as on the steep front. However, a ratio of two or three to one would be expected. The coil to coil voltages also would be higher on the chopped tail but not necessarily in the same ratio.

With regard to actual turn stresses, the first few coils will have turn to turn voltages approximating what is obtained by assuming a 7500-kv-per-microsecond front penetrating the winding in traveling-wave fashion. If the developed length of a turn is, say, 14 feet, the turn voltage will approximate $14/1{,}000 \times 7{,}500 \approx 105$ kv (where 1,000 feet per microsecond is the assumed rate of propagation). Some 10 per cent to 20 per cent from line end tests on coils of this type have shown the turn voltages are one-half or less of those near the line end. The coil to coil voltages have a similar ratio.

My conclusions for the large transformer are

1. That the turn to turn voltages at the line end are not negligible by any means.

2. That the turn to turn voltages at the line end are at least twice as great as in the main body of the winding.

3. That the turn to turn voltages at the line end on the chopped wave tail are at least twice as great as on the steep wave front.

Of course, it should be pointed out that the effect of the rapid voltage decay on the tail of the steep wave is similar to that of the chopped wave. However, Vogel's conclusions are based entirely on the front of the steep wave and the tail of the chopped wave.

This discussion is not an argument for or against steep waves or chopped waves but merely an attempt to show that the author's conclusions are too broad to be drawn from the evidence presented.

F. J. Vogel: I was very much interested in J. H. Hagenguth's discussion, because in previous discussions he brought out the opinion that chopped waves led to high coil to coil voltages and therefore were about as dangerous as stresses on the front of the wave which actually resulted in slightly higher coil to coil voltages. This was as much of a generalization as any I have attempted, and one I do not believe to be true on the basis of this paper.

In presenting my paper, I stated that there had been many statements made which were not generally true, and that in this paper one particular case was presented and analyzed, and logical conclusions for this one case drawn. If this point of view is adhered to, I do not believe that there is too much difficulty in following the first paragraph under "Comparison of Stresses, Initial Distribution of Entering Wave, or Chopped Waves."

However, Hagenguth truly did understand the point made regarding the severity of the stresses between coils as indicated in the second paragraph of his discussion. In the case shown in Figure 6 of my paper, the coil to coil stresses between the line coils are clearly higher in the initial distribution than at any time later. However, as Hagenguth states and later shows, they may be higher provided the line turns are heavily reinforced and oscillated with the main body of the transformer winding. This is not a desirable construction in my opinion; all design engineers may not desire to follow it, and those that do not should not be forced to use unnecessary reinforcing for empirical or other reasons. Thus, fact number one does not apply to the conditions given.

The second fact cited is true, that stresses to ground are produced at edge *C* by chopped waves before chopping, or by full waves also. However, the stress at *B* is lower the higher the actual potential is at *C*, so what of it? In spite of what might appear to be the general tenor of these remarks, I believe that the first steps to agreement have been taken in recognizing the fact that what may be true for one design practice may not be for another. Also, it is not desirable to burden one practice with the requirements of another provided a serviceable design that can be proven is obtained. The latter part of Hagenguth's discussion leads in this direction, and to this I can subscribe completely.

I think J. R. Meador's discussion, too, assumes some statements that were not made. I did not state that the field plots shown were exactly the same as those encountered in a 138-kv design, but I can assure him that the proportions and voltages between coils are in the same order as many that have been designed and tested. How they were obtained can not be de-

scribed in detail because I do not feel that I am free to do it, but his statement as to space factor is his assumption and is not true. Meador is entirely correct in one respect, however. In the case of a very large transformer, few turns per coil may require more turn insulation than in the transformer I described. However, 50 volts per turn could correspond to about 15,000 kva for a 3-phase core-type transformer, which is reasonably large. Because the kilovolt-amperes vary about as the volts per turn squared, 200 volts per turn would be used for a whopper, but Meador did not give figures for the size that he assumed using his design procedure.

I was very much interested in Meador's statements regarding penetration of voltage into the line coils. The methods used are questionable and not entirely sound, but even so I can agree partly to his conclusions and still not seriously invalidate my own reasoning. For example, if we had 50 per cent of the voltage on the chopped wave across two coils, we would have 750 kv divided by 24 between turns, or about 30 kv between turns instead of 105 kv. In this case, the copper would be quite heavy, and the space required by the turn insulation not great in proportion to Meador's use of 1,000 feet per microsecond as a rate of wave penetration is far too small, the surge actually being transmitted much faster because of the capacity between the static plate and the adjacent turns as well as the capacity between turns. The turn-to-turn insulation should be in proportion to the requirements for extemely large units, just the same as the coil-to-coil insulation should be in proportion to the requirements. Incidentally this type of winding might not be used, because parallel paths or windings could reduce the stresses and improve the winding. If Meador's conclusion read that the "turn-to-turn stresses at the line end for extremely large units or heavy currents are not always negligible," it would not conflict violently with the conclusion that turn-to-turn insulation is not the limiting feature "in most cases."

With respect to Meador's third conclusion, it might be noted that a steep front wave has both a front and tail, as he states, and the coil-to-coil insulation still may be stressed more severely on the front of the wave than on the tail.

Again, I wish to give my belief that there is not a complete difference of opinion between these discussions and the content of my paper, but a difference in the extent to which the conclusions can be applied. I think that the study for the revision of dielectric tests for transformers is helped by the discussion. I hope that in this closure I have answered satisfactorily most of the important objections raised.

The Application of Lead Networks and Sinusoidal Analysis to Automatic Control Systems

GEORGE J. SCHWARTZ
ASSOCIATE AIEE

Synopsis: Design considerations relating to the construction of a high performance servomechanism are discussed here. In particular, the improvement in performance that may be achieved through the use of lead networks* and the valuable guides to system synthesis afforded by sinusoidal analysis[1-4] are demonstrated. Direct reference to an armature-controlled d-c motor system** designed by the author is made and its dynamic characteristics are considered in detail in order to show the correlation between theory and practice as applied to a servomechanism design.

ARMATURE-CONTROLLED d-c motor servomechanisms have been built in great quantities during the past five years. In such systems a two stage d-c generator often serves as the primary power source controlling the servomotor. The motor, in turn, is driven by the generator output voltage which is roughly proportional to the error in the closed-cycle system. The simple automatic controller thus formed suffers the inherent limitation of a tendency toward instability for any reasonable degree of static stiffness. Stabilized operation can be attained, however, through the introduction of high-pass degenerative output feedback, often referred to as antihunt control. A servomechanism of this type is indicated in Figure 1. Such systems provide high positioning and following accuracy and it is possible to obtain ratios of input velocity to positional error or lag, commonly called the velocity-error constant, greater than 600 radians per second per radian of error. When still higher accuracy is necessary it may be provided by cascade circuits in the electronic amplifier, which produce additional error compensation or integral control.†

The use of an anticipatory or lead network in conjunction with the output feedback can increase the natural frequency greatly and hence the transient performance of a system. The increased natural frequency of the system often can make possible such an increase in steady-state accuracy that integral control or other error-compensation means are unnecessary.

A detailed consideration of the synthesis and design processes involved in predicting the optimum type and amount of control effects to introduce into a high performance control system is beyond the scope of this paper. This subject already has been treated at length in the literature.[6-9]

The prescribed aim of this paper is to demonstrate, with the aid of transfer loci, the improvement in a d-c motor control system that may be achieved through the use of output feedback and one type of anticipatory network. Only the mathematical preliminaries to the synthesis or analysis of a control system will be considered.

The system to be considered is indicated in Figure 2. The considerations presented in this paper, however, are not peculiar to this type of servomechanism but may be applied to many control systems. The approach offered is particularly applicable to those systems employing dynamoelectric amplification of the Ward Leonard or amplidyne variety.

Although the mathematical analysis presented presupposes a linear system, the same families of transfer loci and resonance curves may be constructed, through physical measurements, for nonlinear systems. Useful guides to nonlinear system design may be obtained by applying the same stability and performance criteria to these experimentally derived curves.

The D-C Motor Servomechanism

The lags resulting from energy storage in the electromagnetic elements and the inertial effect of the power motor and controller output member are the principle factors limiting the transient performance of the simple servo systems represented by Figure 1. These basic systems also display limited response speed and often large transient errors because of the relatively large time constant unavoidably associated with the feed-back and error correction circuits. The system accuracy under sinusoidal and random input conditions improves as the output feed-back time constant is reduced. However, the oscillatory tendencies of the system also are enhanced by shortening this time constant. The accuracy of such systems under transient conditions therefore is determined to a great extent by the degree of stability required.

The delays inherent in the amplifier-generator and the antihunt control associated with it may be compensated

* A lead network is defined as one which introduces a positive phase angle which increases with frequency in the frequency range over which the servo system operates.

** The servo system described in this paper was developed while the author was associated with the servomechanisms laboratory of the Massachusetts Institute of Technology, Cambridge, Mass.

† Integral control may be defined as a control effect whose magnitude is proportional to the integrated effect of all previous errors.

Paper 47-7, recommended by the AIEE committee on instruments and measurements for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted August 16, 1946; made available for printing October 28, 1946.

GEORGE J. SCHWARTZ is with the Arma Corporation, Brooklyn, N. Y.

Figure 1. Armature-controlled d-c motor servomechanism

Figure 2. D-c motor servomechanism with output feedback and cascade lead network

partially through the introduction of anticipation, or derivative action, into the amplifier controlling the fields of the amplifier-generator. The use of either output feedback or lead networks alone may produce tolerable results, but the combined action of both effects in proper proportion can produce excellent operation for a properly adjusted system.

Mathematical Analysis

A mathematical analysis is valuable in predetermining quantitatively a controller design and in explaining various phenomena which appear in the response of the completed system. For more complicated control systems, of which most servomechanisms are typical, the use of the sinusoidal analysis yields a solution which is handled easily and from which results are obtained readily. The transfer functions* provided by the sinusoidal approach are particularly potent in the consideration of servo systems with compensating feedback and lead networks.

The transfer function permits a detailed study of the dynamic characteristics of the various elements of a control system and the product of all the component transfer functions yields the transfer function for the over-all system.

The tranfer function for a physical system will be, in general, of the form

$$\frac{\theta_o(j\omega)}{\epsilon(j\omega)} = F(j\omega) = \frac{K(1+a_1 j\omega)(1+a_2 j\omega)(1+a_3 j\omega)\ldots}{j\omega(1+b_1 j\omega)(1+b_2 j\omega)(1+b_3 j\omega)\ldots} \quad (1)$$

where K, a_1, b_1, and so forth are physical constants of the system, $\theta_o(j\omega)$ is the servo output or response function, and $\epsilon(j\omega)$ is the error function of the complex frequency vector $j\omega$. $\theta_o(j\omega)$ and $\epsilon(j\omega)$ are related to the input or driving function $\theta_i(j\omega)$ by the relationship

$$\epsilon(j\omega) = \theta_i(j\omega) - \theta_o(j\omega) \quad (2)$$

* A transfer function is the vector ratio of the output to input of any physical system specifying the performance of that system as a function of the frequency of its input.

The magnitude of many of the physical constants determining the factors in this expression are at the discretion of the servo designer, and it is possible to modify certain of these factors and to introduce others so as to produce a more desirable transfer function. In regard to the d-c motor systems already described, both the magnitude and time constant of the anticipation and output feedback as well as the amplifier-generator gain, in general, may be varied at will in order to produce optimum performance.

Sinusoidal analysis is especially valuable because the transfer locus, or complex vector plot of the transfer function, clearly depicts the changes in system performance accomplished through the introduction of a wide range of control effects and the variation of certain of the physical constants involved.

Formulation of System Transfer Function

The first step in the analysis of an existing or proposed servomechanism is the formulation of its basic transfer function. The transfer function for the system under consideration will now be derived.

(*a*). The control preamplifier contains a linear voltage amplifier and a compensating or lead network as shown in Figure 3. If the voltage amplifier is assumed to be ideal—constant amplitude and zero phase shift response—the compensated preamplifier can be shown to have a response characterized by the equation

$$\frac{\text{Output voltage}}{\text{Input voltage}} = \frac{E_L}{\epsilon} = K_1 \frac{R_2}{R_1+R_2} \frac{1+R_1C_1 j\omega}{1+\frac{R_1R_2}{R_1+R_2}C_1 j\omega} \quad (3)$$

where K_1 is the constant d-c gain of the voltage amplifier. Other constants are designated in Figure 3.

This expression is simply the transfer function for a linear amplifier with anticipation or derivative control added. If the following quantities are defined:

T_L = lead network time constant

$$= \frac{R_1R_2}{R_1+R_2}C_1$$

A_L = lead network attenuation $= \dfrac{R_1+R_2}{R_2}$

the preamplifier transfer function becomes

$$\frac{E_L}{\epsilon} = \frac{K_2}{A_L}\frac{1+A_L T_L j\omega}{1+T_L j\omega} \quad (4)$$

(*b*). The transfer function for the output feed-back circuit is easily found to be

$$\frac{E_{OF}}{E_O} = \frac{R_3C_3 j\omega}{1+R_3C_3 j\omega} K_3 \quad (5)$$

where K_3 is the percentage of amplifier-generator output voltage fed back.

If the output feed-back time constant is defined as

$$T_{OF} = R_3C_3 \quad (6)$$

then

$$\frac{E_{OF}}{E_O} = \frac{K_3 T_{OF} j\omega}{1+T_{OF} j\omega} \quad (7)$$

(*c*). The transfer function for the amplifier-generator is merely the ratio of armature open-circuit output voltage to control field current. If the generator first-stage control fields are driven from high resistance pentodes the resulting control field time constant is negligible. The only important time delay in the amplifier-generator, therefore, is that effecting the build-up of flux in the fields of the second stage. If, as was done in the system under consideration, the amplifier-generator is compensated completely for cross-magnetization and armature reaction effects, the amplifier-generator-time constant T_A is simply the ratio of armature inductance to resistance. The transfer function for the simplified amplifier-generator becomes

$$\frac{E_O}{I_F} = \frac{K_4}{1+T_A j\omega} \quad (8)$$

Figure 3. Schematic diagram for complete servo system

where

E_O = amplifier-generator open-circuit output voltage

I_F = control field current

K_4 = amplifier-generator gain in volts per ampere

$T_A = L_A/R_A$

(*d*). The derivation of the servomotor transfer function is simplified if the inductance of the motor armature circuit is neglected. In many practical applications this assumption is valid. The following voltage and torque relationships yield the motor transfer function or ratio of shaft angular position to applied armature voltage.

Amplifier-generator generated voltage $= E_O$

$$= K_V \frac{d\theta_M}{dt} + (R_A + R_M) I_o \tag{9}$$

Motor torque =

$$= (J_M + N^2 J_L) \frac{d^2\theta_M}{dt^2} \tag{10}$$

where K_T is the motor torque per unit current, K_V is the motor back electromotive force per unit speed, and $N^2 J_L$ is the effective load inertia reflected to the motor shaft.

From equations 9 and 10

$$E_O = K_V \frac{d\theta_M}{dt} + \frac{(R_A + R_M)(J_M + N^2 J_L)}{K_T} \times \frac{d^2\theta_M}{dt^2} \tag{11}$$

For the case of the sinusoidal functions to be considered here, we may let $j\omega$ represent differentiation with respect to time, hence

$$\frac{d}{dt} = j\omega, \frac{d^2}{dt^2} = -\omega^2, \ldots\ldots$$

Equation 11 may be reduced to

$$\frac{\theta_M}{E_O} = \frac{1/K_V}{j\omega\left[1 + \frac{(R_A + R_M)(J_M + N^2 J_L)}{K_T K_V} j\omega\right]} \tag{12}$$

If we define the output time constant

$$T_o = \frac{(R_A + R_M)(J_M + N^2 J_L)}{K_T K_V} \tag{13}$$

then

$$\frac{\theta_M}{E_O} = \frac{1/K_V}{j\omega(1 + T_o j\omega)} \tag{14}$$

and because

$$\theta_o = N\theta_M \tag{15}$$

$$\frac{\theta_o}{E_O} = \frac{N/K_V}{j\omega(1 + T_o j\omega)} \tag{16}$$

In the special case of an unloaded motor ($J_L = 0$) driven from a zero impedance source ($R_A = 0$) this output time constant simplifies to the basic motor time constant

$$T_M = \frac{R_M J_M}{K_T K_V} \tag{17}$$

(*e*). If the individual control elements of Figure 3, namely, amplifier, feed-back circuit, amplifier-generator, and servomotor, are considered now in their proper physical relationship, the following expression results:

$$I_F = \left[\frac{K_2}{A_L} \frac{1 + A_L T_L j\omega}{1 + T_L j\omega} \epsilon - K_3 \frac{T_{OF} j\omega E_O}{1 + T_{OF} j\omega}\right] K_4 \tag{18}$$

Combining the expression for servo error, $\epsilon = K_1(\theta_i - \theta_o)$, with equations 8, 16, and 18, the complete system transfer function results

$$\frac{\theta_o}{\epsilon}(j\omega) = \frac{NK_1K_2K_3K_4(1/K_V)(1/A_L)}{j\omega(1 + T_o j\omega)\left(\frac{K_3K_4K_5T_{OF}j\omega}{1 + T_{OF}j\omega} + 1 + T_A j\omega\right)} \frac{1 + A_L T_L j\omega}{1 + T_L j\omega} \tag{19}$$

Value of Transfer Function

It should be stressed that the servo-analysis thus far has considered only the system transfer function or ratio of servo output to servo error. No mention has been made yet of what would appear to be the servo designer's primary concern, namely the ratio of servo output to servo input. The emphasis on error rather than input was intentional and is based on the following points:

1. Stability, the fundamental requirement of a servo, depends solely on output as a function of error not of input.

2. The sinusoidal analysis of a servomechanism is based on properties of its system transfer function.

3. If the transfer function of a system is known, the response or output-input vector ratio easily can be derived both graphically and analytically. Consider for example the servo represented in Figure 4*A*. If this system is characterized by a transfer function $\theta_o(j\omega)/\epsilon(j\omega) = F(j\omega)$, then the response function $\theta_o(j\omega)/\theta_i(j\omega)$ is related to the transfer function by the expression

$$\frac{\theta_o}{\theta_i}(j\omega) = F'(j\omega) = \frac{F(j\omega)}{1 + F(j\omega)} \tag{20}$$

A similar relationship exists for a feed-back amplifier having a direct gain or transfer function μ and a feed-back factor $-\beta$. Under these conditions the over-all response or amplification for the amplifier is expressed by

$$\frac{\text{Output voltage}}{\text{Input voltage}} = \frac{\mu}{1 + \mu\beta}$$

The servomechanism is a special case of the feed-back amplifier in which $\beta = 1$.

Figure 4A. Servo block diagram

Figure 4B. Typical servo transfer locus

Consider now the typical transfer locus sketched in Figure 4*B*. The vector *OA* is seen to represent the value of the transfer function $F(j\omega_1)$ while the vector *IA* represents $1 + F(j\omega_1)$ at the angular frequency ω_1. The system response to that frequency therefore is represented by equation 20 and is equal to the ratio of the vector *OA* to the vector *IA*.

Physical Characteristics of Servo System

Having derived the transfer function for the servomechanism, the physical constants of the system should be evaluated next by calculation or measurement. The system under discussion was typical of many power drives in the 1-horsepower class built for military application. The servomotor employed was rated at $^1/_2$ horsepower at a speed of 3,000 rpm and was geared to its output or load member through a reduction of 432 to 1. The inertia of the load was 20,000 pound-feet-squared. A synchro data transmission system operating at 36 times the speed of the load was used to measure error in the system and supply appropriate electrical signals to the electronic control amplifier.

The time constant for the 500-watt amplifier-generator employed was calculated to be approximately 0.02 second. The output voltage was directly proportional to control field current up to 75 per cent of rated output voltage, thus indicating no excessive magnetic saturation in the iron. The generator gain over the linear range was approximately 45 volts per milliampere. The amplifier-generator well represented an ideal generator in displaying an internal resistance of only 20 ohms.

On the basis of the expression previously derived, the servomotor time constant $T_M = R_M J_M / K_T K_V$ was calculated to be 0.024 second. This figure, of course, has no practical significance because the motor as employed in a servo system is coupled to a large inertial load and driven from a generator of finite impedance. The actual output time constant

$$T_o = \frac{(R_M + R_A)(J_M + N^2 J_L)}{K_T K_V} \tag{13}$$

was 0.24 second. The load inertia almost quadrupled the original time constant and the amplifier-generator armature resistance of only nine ohms served almost to triple this figure. The desirability of low load inertia and the importance of designing for low armature resistance are apparent.

The output torque of the servomotor was proportional to motor armature amperes up to one-half of rated current; motor torque sensitivity K_T over this range was approximately 0.47 pound-foot per ampere.

Figure 5. Transfer loci for complete control systems and their individual components

$$F_a(j\omega) = \frac{N}{K_V} \frac{1}{j\omega(1+T_o j\omega)}$$

$$F_b(j\omega) = \frac{K_3 K_4}{1+T_A j\omega}$$

$$F_c(j\omega) = \frac{K_5 T_{OF} j\omega}{1+T_{OF} j\omega}$$

$$F_d(j\omega) = \frac{1+A_L T_L j\omega}{1+T_L j\omega}$$

$$F_e(j\omega) = \frac{1}{\dfrac{K_3 K_4 K_5 T_{OF} j\omega}{1+T_{OF} j\omega} + 1 + T_A j\omega}$$

$$F_A(j\omega) = \frac{N K_1 K_2 K_3 K_4 (1/K_V)(1/A_L)}{j\omega(1+T_o j\omega)(1+T_A j\omega)}$$

$$F_B(j\omega) = \frac{N K_1 K_2 K_3 K_4 (1/K_V)(1/A_L)}{j\omega(1+T_o j\omega)\left(\dfrac{K_3 K_4 K_5 T_{OF} j\omega}{1+T_{OF} j\omega} + 1 + T_A j\omega\right)}$$

$$F_C(j\omega) = \frac{\dfrac{N K_1 K_3 K_3 K_4}{K_V A_L} \quad \dfrac{1+A_L T_L j\omega}{1+T_L j\omega}}{j\omega(1+T_o j\omega)\left(\dfrac{K_3 K_4 K_5 T_{OF} j\omega}{1+T_{OF} j\omega} + 1 + T_A j\omega\right)}$$

The values of pertinent amplifier-generator and control circuit constants are tabulated in Table I.

Sinusoidal Analysis

Having derived the transfer function for the system and determined the values of the unalterable parameters involved, the function should be plotted with the ultimate aim of detecting the effect of the individual components and control effects on the over-all system response.

The manner in which the transfer functions for the individual components combine to produce the complete system locus is indicated graphically in Figure 5. Curves *a*, *b*, *c*, and *d* are plots of the transfer functions for the output members (equation 16), the amplifier-generator (equation 8), the output feedback (equation 7), and the lead network (equation 4), respectively. These curves indicate the general shape of the functions but are not plotted to scale. The arrowheads on the curves indicate the direction of increasing frequency.

Curve *e* is derived from curves *b* and *c* and represents the amplifier-generator lag factor as modified by the re-entrant output feed-back loop. This factor appears in the denominator of the complete system transfer function (equation 19). The mathematical relationship between curves *b*, *c*, and *e* is indicated also in Figure 5.

The elimination of both output feedback and anticipation from our complete control simplifies the system and modifies the transfer function to the basic form

$$\frac{\theta_o}{\epsilon}(j\omega) = \frac{N K_1 K_2 K_3 K_4 (1/K_V)(1/A_L)}{j\omega(1+T_o j\omega)(1+T_A j\omega)} \tag{21}$$

The locus for this function is formed

Table I. Amplifier-Generator and Control Circuit Constants

Motor to load gear ratio	$N = 1/432$
Synchro sensitivity (for 36 speed synchro system)	$K_1 = 2{,}060$ volts per radian
Voltage amplifier gain	$K_2 = 7.1$ (21.3 for curve *C* of Figure 9)
Power amplifier gain	$K_3 = 0.002$ ampere per volt
Amplifier-generator gain	$K_4 = 45{,}000$ volts per ampere
Feed-back factor	$K_5 = 0.5$
Motor torque sensitivity	$K_T = 0.47$ pound-foot per ampere
Motor voltage sensitivity	$K_V = 0.64$ volt per radian per second
Lead network attenuation	$A_L = 11$
Lead network time constant	$T_L = 0.009$ second
Output feed-back time constant	$T_{OF} = 0.50$ second (4.0 seconds for curve *D* of Figures 8 and 9)
Amplifier-generator time constant	$T_A = 0.021$ second
Load inertia	$J_L = 20{,}000$ pound-feet^2
Motor inertia	$J_M = 0.048$ pound-foot^2
Motor armature resistance	$R_M = 5.75$ ohms
Amplifier-generator armature resistance	$R_A = 9.0$ ohms

Figure 6. Transfer loci for d-c motor servomechanism demonstrating effect of output feedback and lead network

A—Basic d-c motor system

$$\frac{\theta_o}{\epsilon}(j\omega) = \frac{432}{j\omega(1+0.24j\omega)(1+0.021j\omega)}$$

B—System with output feedback $T_{OF} = 0.5$ second

$$\frac{\theta_o}{\epsilon}(j\omega) = \frac{432}{j\omega(1+0.24j\omega)\left(\frac{22.5j\omega}{1+0.5j\omega}+1+0.021j\omega\right)}$$

C—System with lead network and output feedback

$T_{OF} = 0.5$ second

$T_L = 0.009$ second

$$\frac{\theta_o}{\epsilon}(j\omega) = \frac{432(1+0.1j\omega)/(1+0.009j\omega)}{j\omega(1+0.24j\omega)\left(\frac{22.5j\omega}{1+0.5j\omega}+1+0.021j\omega\right)}$$

from curves *a* and *b* of Figure 5 and is plotted as curve *A*.

The addition of output feedback to the basic system modifies the transfer function to the form

$$\frac{\theta_o}{\epsilon}(j\omega) = \frac{NK_1K_2K_3K_4(1/K_V)(1/A_L)}{j\omega(1+T_a j\omega)\left(\frac{K_3K_4K_5T_{OF}j\omega}{1+T_{OF}j\omega}+1+T_A j\omega\right)} \tag{22}$$

The locus for this function is the product of curves *a* and *e* and is plotted in Figure 5 as curve *B*.

The complete system function (equation 19) likewise is determined from the vector product of curves *a*, *e*, and *d* and is sketched in Figure 5 as curve *C*. Transfer loci for the complete power drive (equation 19) and its two modifications, (equations 21 and 22), are plotted to scale in Figure 6.

Equations 21 and 22 show that the effect of adding output feedback to the uncompensated system is to change the amplifier-generator lag factor from $(1 + T_A j\omega)$ to

$$1+T_A j\omega+\frac{K_3K_4K_5T_{OF}j\omega}{1+jT_{OF}\omega}$$

The tendency of the output feedback to increase, at low frequencies, the lag introduced in the system by the amplifier-generator may not be completely apparent from these expressions; the transfer loci for this system, however, show this effect with considerable clarity.

Further analysis of the transfer loci can be guided by a few fundamental properties of servomechanisms, feed-back amplifiers, and any closed-loop system. For example, a system is unstable if its transfer function, when plotted from negative to positive infinite frequency, embraces the point $(-1 + j0)$. It also follows that the oscillatory tendencies of a system are indicated by the proximity of its transfer function to the $(-1 + j0)$ point at any frequency. The characteristic of prime importance for a fast servomechanism is that the portion of the transfer locus which most closely approaches this point in the complex plane be of high frequency and that this portion be sufficiently remote from the $(-1 + j0)$ point so that a preset condition of stability is not exceeded.

With these properties of the transfer function in mind, the curves of Figure 6 clearly display the improvement in system performance made possible through the combined action of output feedback and a lead network.

Curve *A* shows the basic uncompensated servo system to be violently unstable unless the system gain or static stiffness is reduced to a small fraction of the value permitted by a well-stabilized system. For any practical purpose this system is useless. Adding the output feedback has a tremendous stabilizing effect and produces a very practical system as indicated by curve *B*. The additional degree of stability and increased resonant frequency required for a high performance system are afforded through the use of the anticipation network. The transfer function for a d-c motor system modified by both output feedback and a lead network is plotted as curve *C*. This transfer locus represents the complete system already described.

These loci are plotted to a logarithmic amplitude scale in Figure 7 in order to describe the transfer functions over a more complete frequency spectrum. The pronounced effect of the output feedback, particularly at low frequencies where it tends to introduce an additional 90-degree lag in the system, is more obvious from these curves. The effect of the lead network is also shown to be concentrated in the relatively narrow band of frequencies about resonance (for normal "fast" systems this band is from $\omega = 10$ to $\omega = 100$).

Curves *B* and *C* are replotted to an expanded scale in Figure 8 to emphasize further the effect of the lead network in the middle or resonant frequency region. Curve *D* of Figure 8 represents a system with output feedback whose time constant T_{OF} has been increased from 0.5 second to 4.0 seconds. As demonstrated by curves *B* and *D*, increasing T_{OF} improves the stability of the system by moving the transfer locus away from the point $(-1 + j0)$. This stabilizing effect may only be continued within narrow limits, however, because an increase in T_{OF} increases the transient errors in the system, and a very large value for T_{OF} introduces other undesirable effects into the system.

A system with long output feed-back time constant ($T_{OF} = 4.0$ seconds) was explored in the course of development of the finally adopted system which had a relatively short output feed-back time constant ($T_{OF} = 0.5$ second) and a lead network. Response curves for these two

systems are plotted as curves C and D of Figure 9.* The use of the lead network permits a much shorter output feed-back time constant and hence a much faster system with no important reduction in stability. These response curves are derived from the algebraic manipulation of equation C of Figure 6, equation D of Figure 8, and equation 20.

Also plotted in Figure 9 as curves C' and D' are measured response curves for the actual systems built in the laboratory in accordance with the design considerations already discussed. The correlation between the theoretically predicted and actually achieved results is indicated.

Another Approach Afforded by Sinusoidal Analysis

It is interesting and instructive to consider in more detail the effect of the various control elements on over-all response. In particular, to consider the contribution of each element to the net amplitude and phase response at any given frequency—this is another approach afforded by sinusoidal analysis.

The transfer function for the simplified system without output feedback or anticipation already has been expressed in equation 21. The phase characteristics of this function are plotted as a function of the driving frequency in Figure 10.

Phase characteristics of the d-c motor system with output feedback are plotted also in Figure 10. This system is represented by the transfer function of equation 22. The effects of the output feedback are demonstrated by these plots.

* The value of the preamplifier gain K_1 employed in the derivation of curve C has been increased to three times the value employed in curve D and in Figures 6, 7, and 8.

Figure 8. Transfer loci of Figure 6 plotted to expanded scale to accentuate characteristics of transfer loci in vicinity of resonance

B and C—See Figure 6
D—System with output feedback
$T_{OF} = 4.0$ seconds

$$\frac{\theta_{ie}}{\epsilon}(j\omega) = \frac{432}{j\omega\left(1+0.24j\omega\right)\left(\frac{180j\omega}{1+4.0j\omega}+1+0.021j\omega\right)}$$

At zero and very low frequencies, the effect of the output feedback is negligible and the entire system displays the low frequency properties of the motor and amplifier-generator alone. As the frequency is increased the feed-back term begins to introduce an increasing negative angle into the transfer locus for the servomechanism and rotating it in a clockwise direction toward the negative real axis (see Figure 7). The action of the output feedback at low frequencies is not unlike that of a cascade integral controller.

At higher frequencies in the vicinity of resonance, the phase characteristic, in the absence of output feedback, introduces an increasing negative phase angle. This effect shifts the transfer locus toward the $(-1 + j0)$ point in the very range of frequencies in which resonance should occur and such phase shift should be avoided. In this range of frequencies, the output feedback rapidly and very effectively decreases the negative phase angle associated with the transfer function. The feedback also permits the use of increased gain in the system in this frequency range. Stability is maintained in the presence of increased gain in the middle frequency range only because of the very material reduction in negative phase shift.

As frequency is increased further into the high frequency range, the output feedback has a progressively diminishing effect; the response of the system once again is determined solely by the amplifier-generator and motor characteristics.

Considering the effects of the individual parameters of the system, a decrease in the output feedback gain K_8 increases the magnitude of the transfer function in the middle range of frequencies and thus changes the scale of the transfer locus at these frequencies. Decreasing feed-back

Figure 7. Transfer loci plotted to logarithmic scale to display low frequency region

C and *D*—Calculated response curves corresponding to transfer loci of curves *C* and *D* of Figure 8

C' and *D'*—Experimental response curves derived from measurements on actual equipment

C'—System with output feedback and lead network ($T_{OF} = 0.5$ second)

D'—System with output feedback alone ($T_{OF} = 4.0$ seconds)

gain also narrows the middle frequency band and alters the position of this band in the frequency spectrum.

A change in the output feed-back time constant T_{OF} also serves to shift the position of the middle range of frequencies but has little effect on the amplitude of the transfer function within this band. By adjusting K_4 and T_{OF}, this middle range of frequencies may be moved until the resonant point lies within its bounds.

An increase in the amplifier-generator gain K_4 improves the frequency response by widening the middle frequency range.

The results of the introduction of anticipation through the use of lead networks is shown also in the curves of Figure 10. It may be seen that the lead network has the effect both of widening the middle frequency range and of introducing large positive angles throughout this entire range. The lead network has the beneficial effect of rotating the transfer locus in the middle range of frequencies farther away from the negative real axis, so that the frequency at which the locus most closely approaches the $(-1 + j0)$ point is of considerably higher frequency than it would be in the absence of this correction. To achieve maximum corrective effect in the vicinity of resonance, the lead network time constant T_L and the attenuation A_L should be adjusted so that maximum positive lead angle is introduced in this region. In the system under consideration, T_L was approximately 0.009 second and A_L was set equal to 11. These constants produce a maximum phase rotation of 58 degrees at a frequency of 4.8 cycles per second.

In the improved system the actual

A, *B*, and *C*—Plots of argument of transfer function as a function of frequency for systems indicated in Figure 6

Figure 11. Servomechanism vector diagram

amplifier-generator time constant T_A was small enough so that a reasonable increase in its magnitude would not have affected the transfer function appreciably. T_A, under these conditions, becomes important only at frequencies considerably higher than those encountered by a servomechanism.

The Experimental Approach

Experimental verification of theoretical curves is both desirable for evaluation of the theoretical synthesis and design and necessary as a guide to recognizing defects and indicating the course of redesign.

Derivation of the transfer locus involves the measurement of the servo output, the system error, and the phase angle between them; the solution of the triangle *ABO* of Figure 11 is therefore necessary. From an experimental standpoint, the triangle *ABO* is solved most easily through the measurement of θ_i, ϵ, and θ_o. The angle *ABO* between θ_o and ϵ, or the argument of the transfer function, may be calculated then by the law of cosines. Unless very precise measurements are made, however, this method is highly inaccurate because at low frequencies ϵ is very small compared to θ_i and θ_o.

The direct measurement of θ_o, ϵ, and the angle *ABO* is more accurate but requires special measuring equipment. These measurements may be made most directly with the aid of a 2-element recording oscillograph giving a simultaneous plot of θ_o and ϵ and the possibility of scaling the phase shift between them.

Experimental derivation of the response, or $|\theta_o/\theta_i|$, curve however is readily obtainable. The only measuring equipment necessary is a stop watch for determining frequency and an oscillograph or other amplitude measuring device. The construction of the response curve simply entails the determination of the amplitude of θ_o and θ_i for a series of frequencies over the desired range. As the quantity ultimately desired is the ratio θ_o/θ_i at each frequency, the determination of the absolute value of either quantity alone is not necessary.

The required sinusoidal inputs may be derived mechanically by a simple scotch yoke or electrically by driving a rotatable transformer at constant speed.

In general, sufficient experimental data may be derived from the response curve so that recourse to an experimental transfer locus is unnecessary. A typical servo development often is based on a design dictated by the theoretical study of transfer loci and enhanced and verified by experimentally derived response curves.

Conclusions

Sinusoidal analysis has been applied to an armature-controlled d-c motor servomechanism in order to suggest a method of analyzing such systems and to demonstrate the very material improvement in system performance which may be achieved through the introduction of lead networks in conjunction with degenerative output velocity feedback. The transfer loci and resonance curves presented evidence this improvement.

Of the several methods of analyzing control systems, the sinusoidal approach offered here is considered one of the most straightforward and expeditious means of predicting the performance of a system and of indicating methods for improvement. Stability considerations based on Routh's criteria[10] often fail to indicate the direction and degree to which system redesign should be concentrated in order to obtain a higher degree of stability. In addition, methods of analysis concerned with the transient or indicial response of a system, notably the classical application of Heaviside operational calculus,[11] often prove much more cumbersome and laborious. In regard to the transfer loci of Figure 9, a high degree of correlation is not necessary in order to substantiate theoretical predictions in a control system design. Saturation effects and other nonlinearities neglected or overlooked generally serve to distort the transfer function and reduce calculated resonant peaks. Of far more importance and a sufficient justification for the analysis however, is a condition as was achieved in this paper, in which both theoretical and experimental curves demonstrate essentially the same effect caused by variation of a particular physical parameter.

Discussion

Robert E. King (Arma Corporation, Brooklyn, N. Y.): The author's paper describes the successful solution of an exacting problem in servomechanism design. However, one of the conclusions stated by the author when applied to servomechanisms generally seems to minimize more than is warranted the effect of ever present nonlinearities.

It is clear that in the case described such nonlinearities as were present were not important because they did not manifest themselves in unwanted resonance peaks. However, this implies that considerable care was taken to obtain gear trains with small back-lash, that coulomb friction was small, that the amplidyne selected showed linear output over its normal operating range, and that the electronic amplifiers likewise were linear over their operating ranges. The resulting assemblage of linear components then performed in accordance with the author's discussion of the pertinent theory. It should be noted that the lack of agreement in the theoretical and experimental response curves shown in Figure 9 of the paper may in part result from nonlinearities.

In many cases the components used in servomechanisms possess linearity for small operating ranges or even none at all. The problem of obtaining specified performance under these conditions may become extremely difficult because the behavior of the servomechanism is so divergent from that expected on the basis of linear theory. It appears, therefore, that all reasonable means of eliminating or minimizing nonlinearities should be employed in the development of a servomechanism in order that the predicted performance based on linear theory may be obtained. Moreover, as the requirements are made more stringent nonlinearities tend to become relatively more important, and they may become the limiting factors in performance.

In the analysis of linear servomechanisms, as in the present case, the advantages of sinusoidal over transient analysis are recognized generally. When, however, the servomechanism has marked nonlinearities the only analytical approach to the stability and performance requirements seems to be through study of the differential equation representing the behavior of the system. In the limited number of cases where any analysis is practicable it is sometimes possible to apply usefully Routh's criteria for stability. Theoretical studies of a few highly nonlinear servomechanisms have been given in the literature.

Finally, because the design and development of a servomechanism for a specific application is a problem of economics as well as engineering, the relative economics of solutions obtained by combinations of analytical studies and experiment probably represents the most important single problem for the designer.

Robert W. Mayer (General Electric Company Schenectady, N. Y.): There are two points in this paper which I should like to discuss. The first point relates to the requirements stated for a high performance system, and the second is the mathematical treatment of the system with output feedback.

Requirements of a High Performance Servomechanism

In many instances it has been stated that the performance of a servo system is increased by extending its frequency response to the higher frequencies. This is not entirely true. Instead, the application of the particular servomechanism determines whether or not its frequency response represents high or low performance. That is, the performance of a servomechanism should be based upon its ability to meet the requirements of its particular application, rather than upon its ability to respond to input motions at high frequencies.

Two different applications may serve as illustrations. First, if a servomechanism is to be used as a portion of the error channel of another servo loop, the problem of stabilizing the over-all loop can be simplified considerably by extending the frequency response of

the component servomechanism beyond that of the other components of the over-all loop. This many times requires a frequency response having cutoff at high frequencies. On the other hand, for applications in which the error signal contains a large amount of noise and smooth operation with low errors is of importance, it is usually desirable to cutoff the frequency response at as low a frequency as possible. Thus, for the latter application a high performance servomechanism would be one which maintained a minimum of error at the lower operating frequency and whose frequency response cutoff as rapidly as possible thereafter in order to minimize the effects of noise. In this case, a servomechanism having a high frequency response would not be considered a high performance servomechanism.

Analysis of Output Feedback

In this paper the analysis indicates that the amplifier-generator open-circuit voltage E_O is applied to the feed-back filter. Such a condition can result only if the armature resistance R_M of the motor is high compared to the internal impedance R_A of the generator; that is, if the motor does not load the generator. This is not the case in this servomechanism. A more accurate solution may be realized, therefore, by considering the effect of this loading on the generator.

Equation 7 of the paper shows

$$\frac{E_{OF}}{E_O}=\frac{K_sT_{OF}j\omega}{1+T_{OF}j\omega}$$

Instead, this should be written as

$$\frac{E_{OF}}{E_{OL}}=\frac{K_sT_{OF}j\omega}{1+T_{OF}j\omega} \tag{1}$$

Where E_{OL} is now the output of the generator modified by the effect of motor loading.

The expression for E_{OL} may be found as follows:

Referring to Figure 3 of the paper and using $j\omega=d/dt$, the amplifier-generator output voltage under load will be

$$E_{OL}=K_Yj\omega\theta_M+R_MI_o \tag{2}$$

But from equation 10 of the paper

$$I_o=\frac{J_M+N^2J_L}{K_T}(j\omega)^2\theta_M \tag{3}$$

And from equation 11 of the paper

$$(j\omega)^2\theta_M=\frac{K_T}{(R_M+R_A)(J_M+N^2J_L)}\times[E_O-K_Yj\omega\theta_M] \tag{4}$$

From equation 14 of the paper

$$K_Yj\omega\theta_M=\frac{1}{1+T_aj\omega}E_O \tag{5}$$

Substituting equation 5 of this discussion into equation 4, and the result into equation 3 and then into equation 2 gives

$$E_{OL}=\frac{1}{1+T_aj\omega}E_O+\frac{R_M}{R_A+R_M}\times\left[1-\frac{1}{1+T_aj\omega}\right]E_O \tag{6}$$

which may be written as

$$\frac{E_{OL}}{E_O}=\frac{1+\left(\frac{R_M}{R_A+R_M}\right)T_aj\omega}{1+T_aj\omega} \tag{7}$$

Substituting this into equation 1 of this discussion gives the proper result for equation 7 of the paper under load, that is,

$$\frac{E_{OF}}{E_O}=\frac{K_sT_{OF}j\omega}{1+T_{OF}j\omega}\cdot\frac{1+\left(\frac{R_M}{R_A+R_M}\right)T_aj\omega}{1+T_aj\omega} \tag{8}$$

The effect of equation 8 is to considerably modify the transfer function in the critical regions about the point $(-1+j0)$. The net result is a corresponding change in the calculated frequency response curves. For the case with output feedback alone and $T_{OF}=4$ sec (curve D) the calculated curve now gives a resonant peak of

$M=1.15$

at frequency

$f=1.11$ cycles per second

This curve agrees quite closely with the experimental result of Figure 9. It also represents for most applications an improvement in performance over the original curve D in as much as the value of M is considerably lower.

For the case with output feedback and a lead network and with K_s three times the value employed in curve D, the calculated curve for Curve C now gives a resonant peak of

$M=1.06$

at frequency

$f=0.8$ cycle per second

The lower value of M, again represents a calculated improvement in performance. However, the calculated results are in error with the experimental results as far as the resonant frequency is concerned. Further examination of the transfer function with the aid of an attenuation phase diagram[1] shows that the experimental curve could not cut off as rapidly as it does in the region following resonance unless additional time constants becomeing effective in that region of higher frequencies were present. Such time constants would, on the other hand, cause very little change in the results of curve D since its resonant frequency is much lower. This leads to the conclusion that possibly there were other smaller time-constants present in the amplifier or motor which should have been included in the analysis to gain more accurate results at higher frequencies.

Reference

1. Fundamental Theory of Servomechanisms (book), L. A. MacColl. D. Van Nostrand Company, New York, N. Y., 1945.

G. J. Schwartz: R. W. Mayer's definition of a high performance servomechanism introduces a consideration of practical importance that is too often neglected in theoretical study. It is indeed advantageous and often necessary for a servomechanism to reproduce faithfully the low frequency components of its input and yet attenuate or smooth the higher frequency components and random noise. This problem generally requires special design consideration and the application of different criteria for high performance. For the system discussed in the paper, however, the more common performance specifications existed so that a servomechanism with high natural frequency and reasonably low amplification was desirable; high performance in this general case implied accurate response at high frequencies.

I am indebted to R. W. Mayer for his more complete treatment of output feedback from the amplifier-generator armature terminals. Mayer's discussion supplements my approximate or simplified treatment because, as he clearly points out, the analysis presented in the paper is only valid in applications in which the motor armature resistance is large compared to the resistance of the amplifier-generator armature. In the example cited, R_A is in fact larger than R_M so that the loading of the generator by the motor must be considered if an accurate representation of the system is to be obtained.

In the development of a high performance servomechanism every effort should be exerted to produce linear components, particularly if the system is to be adaptable to exact mathematical description and analysis. R. E. King's concern over nonlinearities is accordingly well-founded. As indicated in King's references, reasonable linear approximations to pseudo-linear systems may be made. In general, however, Routh's criteria and continuous transient analysis, as well as the sinusoidal approach, break down when applied to highly nonlinear systems and discontinuous servomechanisms of the relay or contactor type, and recourse must be had to the step by step transient solution.

King's remarks on the economic aspects of system development are particularly pertinent, because the economies to be derived from a well-organized combination of analytical and experimental study cannot be overlooked.

Simplified Graphical Method of Computing Thermal Transients

PAUL NARBUTOVSKIH
MEMBER AIEE

DURING RECENT YEARS the operators of electric equipment—power transformers in particular—became increasingly aware of the inherent overload capacity which their equipment has on transient overloads. This capacity is caused by a reservoir for storing up heat generated by the power losses, and this reservoir is always present in the form of conductor copper, iron, and the structural and insulating materials. Although the operation of equipment making use of the transient overload capacity can be done by actually keeping track of the equipment temperature, or by the use of protective relays geared in some way to the copper temperature[1], or both, any planning of the system's loading ahead of time requires a method, and preferably a simple method, of estimating the available overload capacity of the individual pieces of equipment.

A number of simplified methods for computing thermal transients have been offered in the past, both graphical and semigraphical, based on more or less complex charts and possessing different degrees of generality.[2,3,9] Thus, the method described in this paper is not a venture in a new direction. It is believed, however, that the method described herein possesses a degree of simplicity and generality which makes it worthy of offering in addition to the previously suggested procedures.

Late in 1944 the essential feature of this method was suggested by the author to the AIEE transformer subcommittee, and was included in a recently published paper.[4] This publication, however, did not cover the details of the method, nor was the author fully aware at that time of its convenience and possibilities.

Paper 47-10, recommended by the AIEE committee on electric machinery for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted August 2, 1946; made available for printing November 4, 1946.

PAUL NARBUTOVSKIH is an engineer, transformer engineering department, Westinghouse Electric Corporation, Sharon, Pa.

Fundamentals of Thermal Transients

The method described in this paper, as well as any other method, is based on the acceptance of a certain specific law of the transient temperature variation under a fixed load. Generally, although it is not quite accurate, the exponential law, representing theoretical solution for thermal transients under the condition of simple proportionality between the rate of heat dissipation by a hot surface and its temperature rise over the ambient temperature, is accepted because of its convenience. Expressed as a formula for a system consisting of a single thermal reservoir, this law is

$$\theta_t = \theta_i + (\theta_u - \theta_i)(1 - \epsilon^{-t/T}) \qquad (1)$$

where

θ_t = the transient temperature rise above ambient temperature at time t

θ_i = the initial temperature rise at time $t = 0$, caused by a continuous power loss of W_i watts

θ_u = the ultimate temperature rise at time $t = \infty$, if the given loss W_u were allowed for an indefinitely long time

T = the time constant of the apparatus expressed in the same units of time (minutes or hours) as time t, so that the ratio t/T is dimensionless

ϵ = the base of natural logarithms

Equation 1 applies to both heating and cooling transients, depending on whether $\theta_u > \theta_i$, or $\theta_u < \theta_i$, respectively. In the case of an oil-insulated transformer the equation approximately represents either the oil or the windings temperature rise transients taken separately.[5]

Although details of the theory of thermal transients are outside of the scope of this paper, and the reader is referred for information to other publications[6,7,8] a few remarks about computation of θ_i, θ_u, and T from the basic data on the equipment are considered in order to complete the picture.

If not otherwise known, quantities θ_i and θ_u may be computed from the test or design value of the temperature rise at continuous normal rated load θ_0 using equations 2 and 3, the second form of which applies specifically to transformers

$$\theta_i = \theta_0\left(\frac{W_i}{W_0}\right)^n = \theta_0\left(\frac{1+kP_i^2}{1+k}\right)^n \qquad (2)$$

$$\theta_u = \theta_0\left(\frac{W_u}{W_0}\right)^n = \theta_0\left(\frac{1+kP_u^2}{1+k}\right)^n \qquad (3)$$

where

θ_0, θ_i, θ_u = the ultimate temperature rises, corresponding to the continuous losses of W_0, W_i, and W_u watts, respectively

P_i, P_u = the corresponding per-unit-kilovolt-ampere loads

k = the ratio of copper loss to iron loss at rated load

n = the exponent whose value, with a fair degree of accuracy, may be taken as 0.8 for self-cooled and as 1.0 for forced-cooled equipment.

A convenient chart for computing θ_i and θ_u according to equations 2 and 3 was given previously in the technical literature.[3]

The time constant is a composite effect of the heat storage capacity of the equipment, losses, and the ultimate tempera-

Figure 1. Variation of time constant with load conditions as represented by equation 4

ture rise produced by these losses. Equations for computing the time constant for transformers have been given and are conservative.[2,3,5]

In connection with the time constant, it may be mentioned that for self-cooled apparatus the actual thermal transient deviates from that described by equation 1 because of a nonlinear relation between the losses and the temperature rise of a hot surface. It is always possible, however, to find a value of the time constant for any load condition, which, when used with equation 1, will make the approximate exponential temperature curve match the initial slope and the ultimate temperature rise of the actual nonexponential transient temperature curve. If the time constant satisfying this condition is known for some reference load value starting with zero temperature rise, then, for any other load, and starting at any other temperature rise (θ_i), it may be shown (see the appendix) that the time constant will be given by the expression

$$T_u = T_0 \times \frac{\dfrac{\theta_u}{\theta_0} - \dfrac{\theta_i}{\theta_0}}{\dfrac{W_u}{W_0} - \dfrac{W_i}{W_0}} \qquad (4)$$

where

T_u = the corrected value of the time constant for applied loss of W_u watts, causing an ultimate temperature rise of θ_u

T_0 = the reference known value of the time constant obtained with a loss of W_0 watts applied to a cold unit (most conveniently defined for 100-per-cent load starting cold)

θ_u, θ_i, θ_0 = the final temperature rises corresponding to continuous losses of W_u, W_i, and W_0 watts, of which θ_i is the starting temperature for the transient under consideration

An idea of the variation of the time constant with load condition as defined by equation 4 for the value of exponent $n = 0.8$ may be gained by inspection of Figure 1. This graph may be used for determining the time constant from a reference value in the absence of more direct information.

The use of equation 4 complicates the computations of thermal transients. For the practical operating range of overloads and temperature rises, however, the error introduced by using the same value of the time constant is not great. The graphical method of computations described herein is given primarily for this case. With some obvious modifications it will apply equally well to the case when a correction in the time constant is used.

The Graphical Method

The substance of the graphical method described in this paper is in the use of a special co-ordinate paper, on which any exponential transient given by equation 1 plots as a straight line. To accomplish this, the time co-ordinate of this paper is marked with the values of dimensionless function $u = t/T$ to satisfy the following equation of the scale

$$x = l(1 - \epsilon^{-u}) \qquad (5)$$

where

x = distance in inches from the left-hand end of the scale up to the point marked with the value of u

l = total length of the scale in inches up to the value of $u = \infty$

Thus, the time co-ordinate is given in terms of the ratio t/T. This requires a simple multiplication of u by the time constant T in order to obtain the actual values of time, T being known. However, at the same time it makes the paper universally applicable to representing any exponential transient, whether thermal or electrical (RC or RL circuits), as a straight line. The plot will be a straight line regardless of whether the temperature rise above ambient temperature or the actual total temperature including the ambient temperature is represented on the graph.

For a complete representation of a simple transient it is sufficient to know any two points on the time–temperature curve. These points, when plotted on the transient co-ordinate paper and connected by a straight line, will represent a com-

Figure 2. Representation of simple heating and cooling transients on the transient co-ordinate paper

plete thermal transient from the beginning and to the end of time. Thus, starting with a given initial temperature θ_i and computing the ultimate temperature θ_u by the use of equation 3, one may conveniently obtain the required two points. Referring to Figure 2, curve A, let $\theta_i = 50$ degrees centigrade be the starting temperature and $\theta_u = 120$ degrees centigrade be the ultimate temperature at $t = \infty$. A straight line connecting these two points will be a plot of the complete transient. To obtain the temperature at any instant, say, $t = 2^1/_2$ hours, for a transformer whose time constant is 6.5 hours, it is sufficient to compute the ratio $u = t/T = 2.5/6.5 = 0.385$, and read the value of the temperature directly from the graph, $\theta = 72^1/_2$ degrees centigrade.

An inverse problem can be readily solved. Thus, to determine how long the same load can be maintained without exceeding a temperature of 90 degrees centigrade, obtain from the graph $t/T = 0.85$, giving $t = (0.85)(6.5) = 5^1/_2$ hours.

To visualize more systematically what problems may be solved by the use of the simple graph, such as curve A, Figure 2, one must remember that equation 1, which the graph represents, contains five variables—θ_t, θ_i, θ_u, t, and T. If any four of these are known in some way, the fifth one may be found from the graph. No other method can do more.

The same co-ordinate paper, which we may call the "exponential transient co-ordinate paper," will represent cooling curves as straight lines as well. Thus curve B, Figure 2, represents a cooling transient with all load discontinued after reaching a 120-degree-centigrade temperature. The ultimate temperature in this case is the 25-degree-centigrade ambient temperature. Curve C is a cooling curve when the load was reduced to a value leading to 75 degrees centigrade ultimate temperature after reaching 120 degrees centigrade.

Figure 4. Application of the transient co-ordinate paper to the determination of temperature rise θ_1 which occurs after the first application of load in a load cycle consisting of two applications of the same load, with a cooling period in between

Figure 3. Thermal transient caused by a repeated load cycle, represented on the transient co-ordinate paper

Application to Recurrent Load Cycles

The use of the same co-ordinate paper may be extended to more complex problems with which either the operator or the designer of equipment may be concerned. One such case is the computation of transient transformer temperature under a complex load cycle. To illustrate the method as applied to a somewhat hypothetical case, consider Figure 3. It represents a thermal oil transient under a repeated application of load cycle given in Table I, in a power transformer whose oil rise at rated load is 45 degrees centigrade, time constant is $6^1/_2$ hours and the copper-to-iron loss ratio is 2.5 at rated load, operated at 25-degree-centigrade ambient temperature. The first step in plotting the graph of the composite thermal transient is to compute the ultimate temperature rises corresponding to each load, and the values of ratio t/T for values of time at which the load changes. These computations are accomplished using equations 2 and 3 and the results are tabulated in Table I.

The values of $u = 0.308$, $u = 0.615$, and $u = 1.077$ represent the turning points on the graph at which the loads and slopes of the curves change. It will be noted that it is not necessary to draw the transient curve for each load beginning at $t = 0$. It

Table 1

Per Cent Load	Hours Operated	Ultimate Temp Rise, C	Ultimate Temp	Total at End of Period: Time (t), Hours	$u=t/T$
75	2	32.3	57.3	2	0.308
150	2	73.3	98.3	4	0.615
90	3	39.2	64.2	7	1.077

is, rather, possible and convenient to draw the transient curve as one continuous curve for a complete load cycle, each following load period picking up at the point where the previous load period left off. When the load cycle is repeated, the terminal temperature value of the previous cycle is taken as the starting point of the new cycle.

After the preliminary computations of the ultimate temperatures and the turning points are completed, and the data located on the transient co-ordinate paper, the actual plotting of the thermal transient is so simple that any number of successive load cycles may be plotted without taking the pencil off the paper. When the load cycle is long it may have to be subdivided into shorter periods, because the accuracy of the graph is not good for values of $t/T>3$.

Application to More Complex Problems

An example of thermal problem in which a designer of equipment may be interested, and which can be handled by the same method, is illustrated in Figure 4. In this case the problem consists in designing a piece of equipment for the following load cycle:

Full load	$1^1/_2$ minutes
Cooling with all power disconnected	1 hour
Full load	$1^1/_2$ minutes

At the end of this load cycle the hot-spot temperature rise is not to exceed 120 degrees centigrade.

The equipment can be designed properly if the temperature rise during the first period of load application θ_1 is found. The result obviously will depend on the time constant of the equipment, which must be either computed or estimated and is, for the purpose of illustration, $1^1/_2$ hours.

Although the problem of determining θ_1 may be solved analytically, the graphical method is simpler. It consists of merely locating the turning-point values of the ratio t/T on the transient co-ordinate paper, and adjusting the slope of the cooling curve $(\theta_1-\theta_2-0)$ so as to make $\theta_2-\theta_2=\theta_1$ (which is a justifiable approximation, as the load period is very short compared to the time constant). The answer $\theta_1=79^1/_2$ degrees centigrade may now be read.

Some Practical Drawbacks

Although the method of handling computations of transient temperatures described in this paper is simple and flexible and adopts itself to the solution of fairly complex problems, it has one drawback. It requires the use of a special co-ordinate paper which, being new, is not available on the market. It may be recalled, however, that at one time the engineering profession did not have the assistance of the logarithmic co-ordinate paper. The author's experience with the transient co-ordinate paper in printed form has been so gratifying that, in his opinion, the printing of this paper for general distribution would be entirely justifiable.

Appendix. Derivation of Equation 4

The premises on which this formula is based are as follows:

1. The initial rate of temperature change during the transient computed by the exponential equation 1 should be the same as the actual.

2. The initial and the final temperature rises, as obtained from equation 1, should be the same as the actual.

3. The intermediate values of the transient temperature rise are permitted to deviate from the actual.

To use condition 1 just mentioned, the initial rate of temperature change may be obtained from equation 1 and equated to that obtained from the fundamental equation.

The fundamental equation is

$$W_u=W_s+C\frac{d\theta}{dt} \tag{6}$$

where

W_u = the total heating power
W_s = power dissipated by the external surfaces—a variable function of time
C = thermal capacity

From equation 6 the initial rate of temperature rise is

$$\left(\frac{d\theta}{dt}\right)_{t=0}=\frac{1}{C}(W_u-W_i) \tag{7}$$

where

W_i = the power loss which, when supplied continuously, caused the initial temperature rise θ_i, with which the thermal transient started

The initial rate of increase in temperature rise from equation 1 is

$$\left(\frac{d\theta}{dt}\right)_{t=0}=\frac{\theta_u-\theta_i}{T_u} \tag{8}$$

Equating equations 8 and 7, and solving for T_u

$$T_u=C\frac{\theta_u-\theta_i}{W_u-W_i} \tag{9}$$

Eliminating C, from Equation 9 using the value of a reference time constant T_0

$$T_0=C\times\frac{\theta_0}{W_0}$$

The final relation is obtained

$$T_u=T_0\frac{\left(\frac{\theta_u}{\theta_0}-\frac{\theta_i}{\theta_0}\right)}{\left(\frac{W_u}{W_0}-\frac{W_i}{W_0}\right)}$$

It may be noticed that as far as the premises are concerned this expression does not depend on any assumed law of variation of the heat dissipated by a hot surface with its temperature rise.

Discussion

L. A. Finzi (Carnegie Institute of Technology, Pittsburgh, Pa.): It may be mentioned that the problem of thermal transients in a homogeneous body with infinite internal conductivity has been solved by Newton. During the last 40 years an enormous number of papers have been published in the United States and abroad offering simple graphical methods of computation; hence, it is very difficult to add anything new on the subject. Perhaps engineers could not withstand the temptation to work out such procedures just for the sake of their inherent elegance. I have sinned myself along the same line; in a paper published some 15 years ago, while advocating the introduction of two separate time constants for the transformer as a whole and for the windings only, I developed also a kind of nomogram which I seldom have used since. As a matter of fact, the expressions to be computed are not so complicated as to require all this; one may use the slide rule to advantage or simply may refer to a table of exponential functions. If one prefers graphical methods, ordinary semilogarithmic paper may be good enough.

Yet the very abundance of such publications may indicate something else. It may indicate that some need is felt over and over again to make the operator in the field more conversant with the meaning and practical importance of the thermal transient. From this point of view we should congratulate Paul Narbutovskih for his contribution; his special paper has simplicity, and even the most unskilled person should be able to master its mechanism quite rapidly.

However, there may be other difficulties irking the man in the field in addition to those of plain arithmetic; it is possible that he may feel uncertain about the value of the time constant of his transformer. Of course, there are numerous publications giving instructions for its experimental determination, such as the "American Standards for Transformers, Regulators, and Reactors," 1945, but it would be much simpler if the manufacturers made a practice of giving this information along with the other customary specifications; the manufacturers are best qualified for the job because they have design data, test floor facilities, and engineers who are more accustomed to work with these concepts.

The thermal capacity of a piece of apparatus may have considerable practical importance when handling variable loads; in fact, it may become a deciding factor when one has to choose among transformers of different design, which otherwise equally meet the electrical specifications. A good practical knowledge of its meaning may easily result in noticeable savings.

Reference

1. Overloading Oil Immersed Transformers, L. A. Finzi. *Elektrotechnik und Maschinenbau* (Vienna, Austria), 1932, number 46.

P. Narbutovskih: It is the writer's pleasure to acknowledge that, unbeknown to him at the time of submitting his paper for publication, a co-ordinate paper which would plot a thermal transient as a straight line was suggested by L. C. Nichols in 1934, reference 9 of the paper. In his paper Nichols suggests three different co-ordinate papers: one for heating transient in transformer oil; one for cooling transient in transformer oil; and one for either heating or cooling transient in the winding gradient. The first of these papers fits a theoretical thermal transient for a specific case of zero initial temperature rise. The second paper fits a specific case of cooling down to a zero ultimate temperature rise, both papers based on the assumption that the rate of heat dissipation from a hot surface is proportional to the 0.8 power of its temperature rise. The third variety of the co-ordinate paper suggested by Nichols is based on the exponential solution and is identical with that proposed by the writer.

With due regard for the excellent treatment of the subject by L. C. Nichols, the use of several co-ordinate papers appears practically unjustifiable for several reasons.

First, it may be shown that the general case of either heating or cooling transient, when the temperature rise is not proportional to the first power of the heat loss, cannot be represented exactly as a straight line on the co-ordinate paper of this type. The form suggested by Nichols applies exactly only to the case in which the initial temperature rise is zero. When this condition is not satisfied a change of the time scale will be required.

Other reasons against the use of several co-ordinate papers are

1. It unnecessarily complicates the method which is otherwise very simple.
2. It does not lend itself conveniently to handling thermal transients on cyclic loads.
3. It does not apply to forced-cooled transformers.
4. It is not adaptable to more complex problems involving transient temperatures.

In order to compare the relative accuracy of the different methods, Table I was compiled. Each column represents a transient temperature rise at the same instant of time computed by different methods, different columns for different initial and ultimate temperature conditions, as indicated. The methods referred to by letter in the first column are as follows:

A. Exact solution. Because it does not seem possible to obtain this in terms of elementary functions for the general case when the heat loss is not proportional to the first power of temperature rise, this exact solution is obtained here in the following form of an infinite series.

For a heating transient

$$\frac{t}{T_0}=\left(\frac{\theta_u}{\theta_0}\right)^{1-n}\left[\left(\frac{\theta}{\theta_u}\right)+\frac{\left(\frac{\theta}{\theta_u}\right)^{n+1}}{n+1}+\frac{\left(\frac{\theta}{\theta_u}\right)^{2n+1}}{2n+1}+\dots\right]_{\theta_i}^{\theta}$$

$$=\left(\frac{\theta_u}{\theta_0}\right)^{1-n}\sum_{k=0}^{k=\infty}\frac{1}{kn+1}\times\left[\left(\frac{\theta}{\theta_u}\right)^{kn+1}-\left(\frac{\theta_i}{\theta_u}\right)^{kn+1}\right] \quad (1)$$

or a cooling transient

$$\frac{t}{T_0}=\left(\frac{\theta_u}{\theta_0}\right)^{1-n}\sum_{k=0}^{k=\infty}\frac{1}{kn-1}\times\left[\left(\frac{\theta_u}{\theta}\right)^{kn-1}-\left(\frac{\theta_u}{\theta_i}\right)^{kn-1}\right] \quad (2)$$

In the foregoing

t—Time to reach a variable temperature θ

T_0—Time constant for zero initial temperature rise and θ_0 as the final temperature rise (presumably for 100 per cent load, starting cold)

θ_u—Ultimate temperature at $t=\infty$

θ_i—Initial temperature rise at $t=0$

n—Exponent in the relation between the heat loss and the ultimate temperature rise $\frac{W_u}{W_0}=\left(\frac{\theta_u}{\theta_0}\right)^n$. In this case $n=1.25$.

Equations 1 and 2 require no correction in the time constant. Outside of this virtue, needless to say, they are extremely cumbersome to use. Besides, the series converge very slowly except for small values of time.

Other methods used in Table I are

B. Exponential solution, assuming that the temperature rise varies as the first power of loss. No correction in the time constant.

C. Same as *B*, except the time constant is corrected as per Figure 1 in the article.

D. Co-ordinate paper proposed by Nichols for heating transients. No correction in time constant.

E. Same as *D*, except the time constant is corrected as per Figure 1 in the article (which, incidentally, is the same as that suggested in a different form by Nichols).

In Table I of this closure, a temperature rise of 50 degrees centigrade at rated load is assumed.

An interesting conclusion from Table I is that all methods give results that are not too widely different. The use of methods *B* and *D* leads to the least accurate result and, under high overload conditions, may lead to a serious error. Method *E* is precise so long as the initial rise is zero. For all practical purposes, methods *C* and *E* are about equally accurate, giving results very close to those obtained by the exact solution and erring on opposite sides.

L. A. Finzi made a very valid point when he said that the accuracy of computed results depends not only on the method of computation, but on the basic data with which one starts. In regard to the thermal

Table I. Comparison of Oil Temperature in Self-Cooled Transformer, as Computed by Different Methods, in Degrees Centigrade

transients in transformers, these data include the following: the top oil temperature rise, the winding hot-spot gradient, both at rated load, the time constant, and the loss ratio.

These four quantities, with the exception of one (namely, the hot-spot winding gradient to the top oil) may be determined with reasonable accuracy either by direct measurement or by computation. There is, however, no satisfactory and accepted method of determining the hot-spot winding gradient. The usual test procedure by manufactures does not yield this quantity. The AIEE Standards provide an arbitrary hot spot allowance of 10 degrees centigrade over the average winding temperature, measured by resistance. Yet a relatively small error in this quantity may cause a large error in the computed winding hot-spot temperature on high overloads.

In view of these and other uncertainties, the use of the exponential solution for thermal transients appears to be entirely satisfactory. Of course, for actual computations one may prefer to use the available formulas directly. I do not believe in constructing elaborate charts and graphs, to avoid making a simple multiplication or division, a procedure in which many have indulged in the past. But if much labor required in handling exponential functions can be replaced by just a few simple preliminary calculations and a few straight lines drawn on a special co-ordinate paper, such a simplification should be welcomed.

A Comparison of Two Basic Servomechanism Types

HERBERT HARRIS
ASSOCIATE AIEE

IN THE DESIGN of electric servomechanisms for data transmission or for torque amplification applications, a choice must be made for the best means to stabilize the system and for minimizing static and dynamic errors. In this paper, two methods of stabilization which have common application will be compared. Both of these servomechanisms have been analyzed by others,[1-4,6] but not on a comparative basis and not with the introduction of limitations imposed by response delays.

A block diagram of the first type is shown in Figure 1. The servomotor and its load is characterized by an inertia J and a coulomb or dry friction load F. The torque of the servomotor is assumed to be proportional to the amplifier signal but it is delayed by some electromagnetic storage with a time constant T_M.

Motor torque delays may be caused by inductance in the control field of a d-c motor or by a resonant circuit in the control of an a-c motor. Such delays are of the single exponential type in that a sudden change in amplifier signal will produce a change in torque proportional to

$$(1-e^{-t/T_M})$$

The operational transfer function for this type of delay is

$$1/(1+T_M p)$$

In order to stabilize the control loop a lead network with a transfer function

$$\frac{1+T_A p}{1+T_B p}$$

is introduced to transform the error signal. Such a transfer function may be obtained by the RC network shown or by other means. This method of stabilization has evolved from the concept of using an error derivative, but a true derivative cannot be obtained by a network without a delay, as represented by the denominator $(1+T_B p)$.

The second servomechanism system to be discussed is shown in Figure 2. It evolved from the principle of feeding back a signal proportional to the servomotor speed as a means for stabilization. This simple type has the disadvantage that following a constant speed input necessitates a steady-state error or speed lag, as the speed generator will then feed back a constant signal. Introducing the RC network prevents the passage of such a constant signal, but allows the higher frequency stabilizing signals to pass.

Performance Criteria

Prior to undertaking a design analysis of a servomechanism it is well to state specifically what parameters are of interest and to set up criteria of good performance. In the following discussion some statements will be made which are not immediately evident but will be proved later.

In design, the static sensitivity of the system is often of primary importance. If a load torque F is placed on the output shaft it must be balanced by a motor torque proportional to a so-called static or positional error. The gain of the control loop may be expressed in terms of a sensitivity constant K_s which is defined as the motor torque per unit error. Therefore the error required to balance the load F is F/K_s, and usually is specified to be less than a given value. Analysis will show that there is a limit to the value of K_s which depends on the motor inertia J and the delay time T_M. This limit is of vital interest in determining whether a given motor is suitable for a particular application. A parameter τ_s with the dimensions of time is used to relate J to K_s for convenience in expression, but it has little physical meaning.

$$\tau_s^2 = J/K_s \qquad (1)$$

If the input is given a constant acceleration, the error will attain a constant value proportional to the acceleration after transients have died out. This acceleration lag is a good measure of the dynamic errors of these servomechanisms because many common input motions vary with sufficient smoothness that the error will be approximately equal to the sum of the static and acceleration errors. As a measure of the acceleration error, a second parameter τ_a with the dimensions of time is introduced by the relation

$$\text{Acceleration error} = \tau_a^2 \times \text{acceleration} \qquad (2)$$

Analysis will show that the reduction of τ_a^2 also is limited by the motor response delay T_M.

The delay limits the reduction of the parameters τ_s and τ_a because if T_M is relatively too large, either the servomechanism will be unstable or the oscillations introduced during a transient disturbance will damp too slowly. Therefore, another criterion for good performance is the specification of a certain maximum number of cycles required for an oscillatory "mode to" decay. Alternatively it is satisfactory to specify a maximum value for the resonance peak which measures the amplitude of the output steady-state oscillations for a unit sinusoidal input, at any frequency. As the sinusoidal analysis is the basis for this discussion, it is de-

Paper 47-F2, recommended by the AIEE committee on instruments and measurements for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted August 19, 1946; made available for printing November 7, 1946.

HERBERT HARRIS is in the research laboratories of Sperry Gyroscope Company, Inc., Great Neck, N. Y.

TYPICAL LEAD NETWORK

$$\frac{e_2}{e_1} = \frac{R_2}{R_1+R_2}\,\frac{1+R_1C_1p}{1+R_1C_1\frac{R_2}{R_1+R_2}p} = \frac{T_B}{T_A}\,\frac{1+T_Ap}{1+T_Bp}$$

Figure 1. Servomechanism stabilized by lead network

sirable to introduce this concept and its use more carefully.

The characterizing feature of a closed cycle servomechanism is that an error signal e, which is the difference between the input (or desired output) x_i and the actual output x_o, is used for controlling motor torque. Thus

$$e = x_i - x_o \tag{3}$$

and

$$\frac{x_i}{x_o} = \frac{e}{x_o} + 1 \tag{4}$$

If the input motion x_i is an oscillation of fixed frequency and amplitude for a sufficient time to allow transients to die out, both x_o and e will be oscillations of the same frequency but with different amplitudes and phases. Under these circumstances x_i/x_o and e/x_o may be considered as complex numbers or vectors of magnitude equal to the ratio of the two amplitudes of oscillation, and of an angle with respect to the real axis which is equal to the phase difference between the two oscillations. These two ratios are inverse transfer functions because they represent the ratio of input to output rather than the usual output to input ratio. The use of inverse functions is principally a matter of convenience.[4,5]

At very low frequencies the output will follow the input quite well and the ratio of the two amplitudes will be near unity. At very high frequencies the output will be unable to follow the input so that the magnitude of the transfer function x_o/x_i will approach zero while $|x_i/x_o|$ approaches infinity. At some intermediate frequency range a resonant peak is likely to occur at which the output amplitude is greater than the input amplitude. Thus $|x_o/x_i| > 1$ and $|x_i/x_o| < 1$. If this resonant peak is too high then after any transient disturbance the output will tend to oscillate at a frequency near resonance and damp very slowly. The choice of an allowable value for the resonant peak is partly a matter of experience and partly a matter of correlation between the transient method of analysis and the frequency response method.

For this paper a maximum value for $|x_o/x_i|$ of 1.25 or a minimum value for $|x_i/x_o|$ of 0.8 has been chosen as a performance criterion. This value, of course, is somewhat arbitrary, but the justification is presented that if higher values are chosen, any accidental variation of design parameters will produce a rapid deterioration of performance, while 1.25 still allows appreciable tolerances.

Because e/x_o may be interpreted as a complex number or vector it may be plotted as a point, for one frequency, on the complex plane as shown in Figure 3. Then in accordance with equation 4, the vector x_i/x_o may be interpreted as the vector to this point from the point $(-1+j0)$. As the criterion for satisfactory damping is to be that the magnitude of x_i/x_o should never be less than 0.8 at any frequency, it is necessary that the vectored point should not fall inside the circle of radius 0.8. The procedure for analysis shall be to draw the locus of all these points for e/x_o as the frequency varies, and to observe whether the locus cuts into the circle. The frequency for each point may be written along the locus for reference purposes.

Lead Network Stabilization

The inverse loop transfer function e/x_o for the system of Figure 1 is

$$\frac{e}{x_o} = \frac{1+T_Ap}{1+T_Ap} \times \frac{1+T_Mp}{1} \times \frac{Jp^2}{K_s} \tag{5}$$

in which p is the conventional operator representing differentiation with respect to time. T_B and T_A have the dimensions of time and are network design parameters.

For a frequency response analysis the complex inverse transfer function e/x_o may be obtained from equation 5 by setting $p = j\omega$. For convenience in obtaining a general form suitable for many other servomechanisms, a time τ_o is defined by the relation

$$\tau_o^2 = \frac{J}{K_s} \tag{6}$$

and a nondimensional measure of angular

Figure 2. Servomechanism stabilized by speed feedback through a high-pass filter

HIGH PASS FILTER:

$$\frac{e_2}{e_1} = \frac{RCp}{1+RCp} = \frac{T_Np}{1+T_Np}$$

frequency λ is introduced such that

$$p = j\omega = j(\lambda/\tau_o) \tag{7}$$

The reasons for the choice of τ_o are discussed later. With the substitution from equation 7, equation 5 becomes

$$\frac{e}{x_o} = -\lambda^2 \frac{1+j(T_B/\tau_o)\lambda}{1+j(T_A/\tau_o)\lambda} \times \frac{1+j(T_M/\tau_o)\lambda}{1} \tag{8}$$

This inverse transfer function now can be investigated generally in terms of the three nondimensional ratios T_B/τ_o, T_A/τ_o, and T_M/τ_o. Plots of e/x_o for all possible values of the three ratios involve many curves so that only a few typical ones are shown in Figures 4 and 5. The results obtained from the general curves may be summarized as follows (with a tolerance of about ± ten per cent).

T_B/τ_o and T_M/τ_o represent delays of a similar character, and large values tend to produce a high resonant peak. T_A/τ_o is the stabilizing factor in the system, and if it is too small the resonant peak will be too high.

For a criterion of $|x_i/x_o| > 0.8$, $T_A/\tau_o = 1.5$ is a minimum value even if the delays are zero. For $T_A/\tau_o = 2$, which represents the often quoted critically damped case for a system with negligible delays, the sum of T_B/τ_o and T_M/τ_o may be as high as 0.2, with any division between the two for $|x_i/x_o| > 0.8$. For $T_A/\tau_o = 3$, the sum of the two delays may be as high as 0.25. For higher values of T_A/τ_o the allowable delays gradually decrease, so that for $T_A/\tau_o = 6$, a single delay of 0.19 or two equal 0.06-second delays are satisfactory.

In design the ratios T_A/τ_o and T_B/τ_o are subject to adjustment by the circuit element values of the lead network (Figure 1). By adjustment of the capacitor, T_A and T_B may be varied proportionately within a range such that T_A is not so small as to give insufficient damping nor T_B so large as to make the delay excessive.

Figure 3. Relation of e/x_o to x_i/x_o

T_B may be made small relative to T_A by using a large ratio between the resistors R_1 and R_2, but this is limited by the loss in gain which must be compensated by the amplifier and by the increase in noise level as discussed later.

T_M however, is determined by the motor and is more or less fixed. Therefore, T_M/τ_o is determined by τ_o, and because T_M/τ_o is limited in all cases to less than 0.25, this implies a limitation on the static sensitivity according to equation 6.

The acceleration lag is also of interest and may be determined directly from the differential equation 5 by setting $x_o = 1/2\, at^2$ representing a constant acceleration and finding the constant error which can maintain this acceleration ($de/dt = 0$). Then

$$e + T_A \frac{de}{dt} = \frac{J}{K_s}\left[T_M T_B \frac{d^4}{dt^4} + (T_M + T_B)\frac{d^2}{dt^2} + \frac{d^2}{dt^2}\right]\left(\frac{1}{2}at^2\right) \tag{9}$$

$$e = \frac{J}{K_s}\, a \tag{10}$$

so that according to equation 2

$$\tau_s^2 = \frac{J}{K_s}. \tag{11}$$

Therefore, according to equations 1, 6, and 11, and the summary of inverse transfer function plots, Table I may be presented.

Speed Feedback Through a High-Pass Filter

In the stabilization scheme of Figure 2, a signal proportional to the output speed is fed back through a high-pass filter to oppose the error signal. A typical high-pass filter is the network shown.

If the high-pass filter is removed, a signal proportional to the speed will be fed back and for constant speed output this signal will have to be balanced by an error signal or speed lag. Therefore, T_G is measured in equivalent radians error per radian per second output speed and has the dimension of time. The high-pass filter is introduced to remove this speed lag and it has a time constant T_N determined by the network circuit constants.

It is well known that for the simple servomechanism without the filter, the speed feedback as determined by T_G must have a certain minimum value for well-damped response. In fact,

$$T_G/\tau_s = T_G \Big/ \sqrt{\frac{J}{K_s}} = 2$$

corresponds to the usually quoted critically damped case when no delays are present. The following analysis determines the effect of the delay T_M and the proper values for T_N and T_G.

The inverse transfer function e/x_o is derived from Figure 2 as

$$\left[e - \frac{T_N p}{1+T_N p} \times T_G p \times x_o\right]\frac{K_s}{1+T_M p} = Jp^2 x_o = \text{torque} \tag{12}$$

$$\frac{e}{x_o} = \frac{Jp^2}{K_s}(1+T_M p) + \frac{T_N T_G}{1+T_N p}\, p^2 \tag{13}$$

τ_s^2 again is defined according to equation 1 as J/K_s and subject to later justification τ_o will be defined by

$$\tau_o^2 = \tau_s^2 + T_G T_N \tag{14}$$

$$(\tau_s/\tau_o)^2 = 1 - (T_G/\tau_o)(T_N/\tau_o) \tag{14a}$$

Placing

$$p = j\omega = j(\lambda/\tau_o) \tag{15}$$

in equation 13 there results

$$\frac{e}{x_o} = -\lambda^2(\tau_s/\tau_o)^2[1+j(T_M/\tau_o)\lambda] - \lambda^2\frac{(T_N/\tau_o)(T_G/\tau_o)}{1+j(T_N/\tau_o)\lambda} \tag{16}$$

or by equation 14a

$$\frac{e}{x_o} = -\lambda^2(\tau_s/\tau_o)^2[1+j(T_M/\tau_o)\lambda] - \lambda^2\frac{1-(\tau_s/\tau_o)^2}{1+j(T_N/\tau_o)\lambda} \tag{17}$$

Combining certain terms in equation 17 yields

$$\frac{e}{x_o} = \left[-\lambda^2\frac{1+j(T_N/\tau_o)(\tau_s/\tau_o)^2\lambda}{1+j(T_N/\tau_o)\lambda}\right] - j\lambda^3(T_M/\tau_o)(\tau_s/\tau_o)^2 \tag{18}$$

The portion of equation 18 in the brackets remains even if the delay T_M/τ_o is zero, and it is analogous in form to equation 8 without delay T_M/τ_o. This is a justification for the choice of τ_o according to equation 14.

Table I. Design Values for a Servomechanism Stabilized by a Lead Network

(a). $\tau_s^2 = \tau_o^2 = \tau_o^2 = J/K_s$

(b). $T_A/\tau_o > 1.5$ if negligible delays are present, but greater than 2 and preferably near 3 if delays are present. This is not a critical condition.

(c). $T_B/\tau_o + T_M/\tau_o \leq 0.25$ leading to

(d). $\tau_o > 4T_M$ as a delay limitation on the static sensitivity and the reduction of acceleration lag.

Figure 4. Inverse transfer functions e/x_o for servomechanism stabilized by lead network

$T_A/\tau_o = 2$

Curve	(a)	(b)	(c)	(d)	(e)	(f)	(g)	(h)	(i)
T_B/τ_o	0	0.1	0.2	0.3	0.4	0.5	0.1	0.2	0.3
T_M/τ_o	0	0	0	0	0	0	0.1	0.1	0.1

By analogy with the preceding discussion for a lead network servomechanism the following summary in round numbers may be made, if $T_M/\tau_o \rightarrow 0$:

T_N/τ_o should be at least 2

If $T_N/\tau_o \approx 2$, $(\tau_s/\tau_o)^2$ should be less than $\frac{0.2}{2} \approx 0.1$

If $T_N/\tau_o \approx 3$, $(\tau_s/\tau_o)^2$ should be less than $\frac{0.25}{3} \approx 0.08$

If $T_N/\tau_o \approx 6$, $(\tau_s/\tau_o)^2$ should be less than $\frac{0.19}{6} \approx 0.03$

Because $(\tau_s/\tau_o)^2$ should be less than 0.1, $(T_G/\tau_o)(T_N/\tau_o)$ should be between 0.9 and 1.

Before discussing the effect of the delay T_M/τ_o it is well to interpret the above relations physically. Assuming that T_N and T_G have been set at suitable values according to the condition just mentioned, consider the effect of a variation in the various parameters in conjunction with equation 14.

If the generator voltage T_G is decreased, τ_o^2 will decrease also and eventually $(\tau_s/\tau_o)^2$ will become too large representing too little generator damping and having the same effect as too much delay in the lead network system. If T_G is increased, τ_o will increase, and although $(\tau_s/\tau_o)^2$ will become smaller, T_N/τ_o may become too small. Again there will be too little damping, but in this case it is due to the increased generator voltage increasing the natural period τ_o to such a point that the stabilizing signals cannot pass through the filter in proper phase. This type of resonance often may go unnoticed because of its long period.

If T_N is reduced, τ_o will decrease but at most as the square root so that T_N/τ_o will become too small and $(\tau_s/\tau_o)^2$ too large. If T_N is increased, τ_o will increase almost as the square root, and no harm will be done except to make the system slower and increase the acceleration lag.

If T_N is increased as T_G is decreased inversely, τ_o will remain fixed, and eventually $(T_N/\tau_o)(\tau_s/\tau_o)^2$ will become too large, representing too much delay. Thus a large network time constant cannot make up for a deficiency in generator voltage.

In order to determine the effect of a motor delay T_M/τ_o, it is possible to take plots such as those in Figures 4 and 5 and add the last term of equation 18 for various values of T_M/τ_o. As an example, $T_N/\tau_o = 2$ and $(\tau_s/\tau_o)^2 = 0.05$ yield the same plot as curve *b* in Figure 4. Figure 6 shows the added effect of various values of T_M/τ_o for this same case. In this case T_M/τ_o must be less than about 0.25 in order to remain outside the circle $|x_i/x_o| = 0.8$.

The following summary in round figures may be made of several sets of such curves:

$$\left.\begin{array}{ll}
(a). & \text{If } (\tau_s/\tau_o)^2 \approx 0.1,\ T_M/\tau_o \text{ may be as high as 0.18 if } T_N/\tau_o = 2 \\
(b). & \text{If } (\tau_s/\tau_o)^2 \approx 0.08,\ T_M/\tau_o \text{ must be zero if } T_N/\tau_o = 3 \\
(c). & \text{If } (\tau_s/\tau_o)^2 \approx 0.067,\ T_M/\tau_o \text{ may be as high as 0.25 if } T_N/\tau_o = 2 \\
(d). & \text{If } (\tau_s/\tau_o)^2 \approx 0.05,\ T_M/\tau_o \text{ may be as high as 0.25 if } T_N/\tau_o = 2 \\
 & \text{If } (\tau_s/\tau_o)^2 \approx 0.05,\ T_M/\tau_o \text{ may be as high as 0.13 if } T_N/\tau_o = 3 \\
(e). & \text{If } (\tau_s/\tau_o)^2 \approx 0.033,\ T_M/\tau_o \text{ may be as high as 0.27 if } T_N/\tau_o = 2 \\
 & \text{If } (\tau_s/\tau_o)^2 \approx 0.033,\ T_M/\tau_o \text{ may be as high as 0.15 if } T_N/\tau_o = 3
\end{array}\right\} \quad (19)$$

In general, approximately the same limitation applies to the motor delay in this type of servomechanism as in the lead network type, namely

$$T_M/\tau_o < 0.25 \qquad (20)$$

Equation 13 shows that the lag for a constant acceleration output motion is $(\tau_s^2 + T_G T_N)$ times the acceleration, thus

$$\begin{aligned} \tau_a^2 &= \tau_s^2 + T_G T_N \\ &= \tau_o^2 \end{aligned} \qquad (21)$$

Therefore Table II for this type of servomechanism is equivalent to Table I for the lead network type.

Figure 5. Inverse transfer functions e/x_o for servomechanism stabilized by lead network

$T_A/\tau_o = 3$

Curve	(a)	(b)	(c)	(d)	(e)	(f)	(g)
T_B/τ_o	0	0.1	0.2	0.3	0.4	0.1	0.2
T_M/τ_o	0	0	0	0	0	0.1	0.1

Experimental evidence leads to an even more detailed analysis of this system. If T_G and T_N are increased together, τ_o^2 will increase also so that T_G/τ_o and T_N/τ_o will remain almost constant, but $(\tau_s/\tau_o)^2$ and T_M/τ_o will decrease. This leads to the supposition that the system will become slower but no other trouble will appear. Experimentally, however, the system usually begins to oscillate at a high frequency. This led to an investigation of the effect of a second delay in addition to the motor delay and to the interesting discovery that when $(\tau_s/\tau_o)^2$ is very small the system becomes extremely sensitive to these secondary delays

With a second delay of cT_M seconds in cascade with the motor delay, the inverse transfer function given by equation 18 becomes

$$\frac{e}{x_o} = \left[-\lambda^2 \frac{1 + j(T_N/\tau_o)(\tau_s/\tau_o)^2\lambda}{1 + j(T_N/\tau_o)\lambda} \right] - j\lambda^2(c+1)(T_M/\tau_o)(\tau_s/\tau_o)^2 + \lambda^4 c(T_M/\tau_o)^2(\tau_s/\tau_o)^2 \qquad (22)$$

In this case, plots similar to those of Figure 6 may be used with the last term added. Because the first delay acts to bring the locus down to intersect the negative real axis at some high frequency, and the second delay shifts the locus at this fre-

Table II. Design Values for a Servomechanism Stabilized by Speed Feedback Through a High-Pass Filter

(a). $\tau_s^2 = J/K_s$; $\tau_a^2 = \tau_s^2 = \tau_s^2 + T_G T_N$

(b). T_N/τ_o near 2 allows a maximum delay and is satisfactory for zero delay

(c). $\tau_o > 4T_M$ is the delay limitation

(d). $(\tau_s/\tau_o)^2$ less than about 0.09 if the delay is small, and less than about 0.067 if it is appreciable

Table III. Allowable Values of Secondary Delay in a Servomechanism Stabilized by Speed Feedback Through a High-Pass Filter

$(\tau_s/\tau_o)^2$	τ_M/τ_o	Max Value of Secondary Delay $c\tau_M/\tau_o$ for $\lvert x_l/x_o\rvert \geq 0.8$	Max Value of Secondary Delay $c\tau_M/\tau_o$ for Stability
0.1	0.18		
0.067	0.1	0.09	0.21
	0.2	0.025	0.10
	0.25	0	0.08

0.02	0.1	0.031	0.045
	0.2	0.013	0.03

quency along the real axis in the positive direction, there is the possibility that the $|x_l/x_o|=0.8$ circle may be crossed at some high frequency. If the second delay is sufficiently large, the locus may even go through a point to the right of (-1) representing instability.

As an example of this sensitivity to a second delay Figure 7 contains a series of plots with the following values:

$(\tau_s/\tau_o)^2=0.02$
$T_N/\tau_o=2$
$T_M/\tau_o=0.2$
$c=0.05, 0.1, 0.15$

With zero secondary delay the characteristic does not go near the circle $|x_l/x_o|=0.8$, but with a second delay of only $c=0.07$ units relative to the first it crosses the circle, and with a delay of only $c=0.15$ the system is unstable. Because secondary delays of such small value are likely to be neglected, it is important to recognize this sensitivity. The frequency of resonance is so high ($\lambda>10$) that in some applications higher resonances will be allowable, and even systems just on the verge of instability may be acceptable.

Table III is a rough summary of data taken from several sets of such curves ($T_N/\tau_o=2$).

In some cases the second delay will be in the generator feed-back portion of the loop rather than in the forward part. The effects of the two types of delay are very similar and the allowable values are nearly the same for the smaller values of $(\tau_s/\tau_o)^2$.

The Effect of Internal Damping

Some loads have a viscous friction component which requires a torque proportional to speed, and some motors have a torque-speed characteristic with the torque dropping linearly with speed. Both of these characteristics may be treated in the same way and shown to produce a stabilizing or damping action. Some instrument servomechanisms of low performance make considerable use of this type of damping, but it represents a secondary effect only for servomechanisms which are pushed to design limits and must deliver appreciable power to a load. The latter case will be considered here.

The following relation between motor torque and output motion holds:

$$\text{Torque}=Jp^2x_o+fpx_o$$
$$=p^2J(1+f/Jp)x_o \tag{23}$$

where f is the torque per unit speed required by the load, or the drop in torque per unit speed of the motor as measured at the load shaft.

With this new relation, equations 8 and 16 for e/x_o for the lead network stabilization and the speed feed-back stabilization become

$$\frac{e}{x_o}=\frac{\lambda^2[1+j(T_B/\tau_o)\lambda]}{1+j(T_A/\tau_o)\lambda}\times\frac{1+j(T_M/\tau_o)\lambda}{1}\times\frac{1-j(f/J)(\tau_o/\lambda)}{1} \tag{24}$$

and

$$\frac{e}{x_o}=-\lambda^2[1-j(f/J)(\tau_o/\lambda)][1+j(T_M/\tau_o)\lambda)(\tau_s/\tau_o)^2]-\lambda^2\frac{1-(\tau_s/\tau_o)^2}{1+j(T_N/\tau_o)\lambda} \tag{25}$$

Although the exact method for treating these equations is to make plots for all values of the parameters, it is possible to reason the effect of f for certain special cases. One way is to look at the factor $(f/J)\tau_o$ as a partial compensation for the motor delay T_M/τ_o. Thus

$$[1+j(T_M/\tau_o)\lambda][1-j(f/J)(\tau_o/\lambda)]=[1+(T_M/\tau_o)(f/J)\tau_o]+j[(T_M/\tau_o)\lambda-(f/J)(\tau_o/\lambda)] \tag{26}$$

In equation 24 for the lead network type, the delay factor acts principally as a phase shift which tends to bring the plot inside the $|x_l/x_o|=0.8$ circle at frequencies in the region around $\lambda=2$ for $T_A/\tau_o=3$ and around $\lambda=1$ for $T_A/\tau_o=2$, from Figures 5 and 4. If discussion is limited to the cases for which T_M/τ_o and $(f/J)\tau_o$ are only a few tenths, the angle of this phase shift according to equation 26 is approximately $[(T_M/\tau_o)\lambda-(f/J)(\tau_o/\lambda)]$ radians. Consequently near $\lambda\approx1$ a portion of T_M/τ_o equivalent to $(f/J)\tau_o$ is compensated, and near $\lambda\approx2$ a portion equivalent to $1/4(f/J)\tau_o$ is compensated. Thus the allowable motor delay may be increased by these amounts. If the motor delay is negligible, this damping may be looked upon as compensating some of the delay T_B/τ_o or allowing a reduction of some of the stabilizing lead T_A/τ_o.

For the speed feed-back case the effect is slightly different. As the motor delay causes a resonance at high frequencies near $\lambda=5$ in this case, the term $(f/J)(\tau_o/\lambda)$ becomes very small compared to $(T_M/\tau_o)\lambda$. Consequently there is very little delay compensation. However, it does allow higher values for $(T_N/\tau_o)(\tau_s/\tau_o)^2$ or lower values for T_N/τ_o because these are analogous to T_B/τ_o and T_A/τ_o.

Near zero frequency the term $(f/J)(\tau_o/\lambda)$ becomes predominant and the e/x_o plot starts upward along the imaginary axis rather than in the negative direction on the real axis as before. This represents a phase slope at zero frequency for x_l/x_o which is equal to $(f/J)\tau_o^2=f/K_v$. This slope may be shown to equal the lag error per unit velocity for these servomechanisms and indicates why $(f/J)\tau_o$ is small in high performance systems. This speed lag constant f/K_v will determine the necessary value for K_v in some cases rather than either the static or acceleration error limit.

The Transient Response

The justification for setting up criteria for good dynamic response on a frequency analysis basis is that solutions on this basis take considerably less calculation time and give essentially the same results as a transient analysis. Nevertheless it is of interest to show a few transient responses for comparison with corresponding frequency responses.

When the motor delay T_M/τ_o is negligible, the two types under discussion have the same transfer function and differen-

Figure 6. Inverse transfer functions e/x_o servomechanism stabilized by speed feedback through a high-pass filter

$T_N/\tau_o=2$, $(\tau_s/\tau_o)^2=0.05$

tial equation with the following parameters analogous:

$$T_A/\tau_0 \longrightarrow T_N/\tau_0$$
$$T_B/\tau_0 \longrightarrow (T_N/\tau_0)(\tau_s/\tau_0)^2$$
$$T_B/\tau_A \longrightarrow (\tau_s/\tau_0)^2$$

Consequently they will have the same transient responses.

Figure 8 shows the error as a function of time resulting from a suddenly applied input velocity of n radians per second for the case of $T_A/\tau_0=2$ and several values of T_B/τ_0. It will be observed that for $T_B/\tau_0=0.2$ the oscillatory character is barely distinguishable, but it is definitely present for $T_B/\tau_0=0.4$. In the frequency response, $T_B/\tau_0=0.2$ gives a resonant peak $|x_o/x_i|$ of about 1.25, which has been considered good performance, while for $T_B/\tau_0=0.4$ the resonant peak is slightly over 1.5. Thus there is general agreement in the two methods. Sometimes it will be found that simple transient responses mask some of the oscillatory character which is accentuated when several similar servomechanisms are interacting in a common system and two resonant servomechanisms are in cascade.

It is also to be observed that the error peak is roughly $1/2\,n\tau_0$ and that the time required for the transient to die out is about $4\tau_0$ seconds. Therefore there is a dual advantage to making τ_0 low, and the reason for the definition of τ_0 in this particular way is that several different servomechanisms may be placed on a similar basis for comparison. τ_0 has another interpretation in that it is near $1/2\pi$ times the period of oscillation with poor stabilization (T_A/τ_0 or T_N/τ_0 too small).

Figure 7. Inverse transfer functions e/x_o for servomechanism stabilized by speed feedback, with secondary delay

$T_N/\tau_0=2$
$(\tau_s/\tau_0)^2=0.02$
$T_M/\tau_0=0.2$

Figure 8. Transient response to a suddenly applied input velocity

Servomechanism stabilized by lead network, with motor delay

A suddenly applied change in input velocity is a fairly severe disturbance which is not often met in practice. Usually the input motion will be fairly smooth in that there will not be any large changes of acceleration in less than $4\tau_0$ seconds (the transient time), so that the dynamic error will be very closely equal to τ_a^2 times the acceleration. Therefore, the quantity τ_a^2 is a good measure of the dynamic performance of the servomechanism. In the two cases considered τ_s is equal to τ_a, but there are other types which have quantities analogous to τ_s and τ_a but not equal. Therefore, two different symbols have been used to maintain the distinction.

Comparison of the Two Types

The analysis has brought out the fact that the dynamic response can be made essentially the same for the two types, and that improvement in performance is limited by the motor delay according to the relation

$$\tau_0=\tau_s>4T_M$$

As a consequence of this there is little choice between the two if high-speed dynamic response is the difficult specification to meet.

The sensitivity to positional or static errors, however, is different for the two types. For lead network stabilization τ_s is equal to τ_s and limited by the same factor, and therefore $K_s=J/\tau_s^2$, the torque per unit error, is limited by

$$K_s<J/16T_M^2$$

For the speed feed-back type, τ_s^2 must be at least about 11 times smaller and could be many times less than this, limited only by the existence of secondary delays. Consequently, if high static sensitivity is the difficult specification to satisfy, the latter type is preferable.

Because servomechanisms are essentially low-pass filters, they will not follow disturbances which have frequency components above a certain frequency which is proportional to $1/\tau_0$, depending upon how the band width of response is defined. Consequently for equivalent static sensitivities the speed feed-back type is a better filter and has smoother response in the presence of high-frequency spurious error signals. This is sometimes a desirable characteristic when the error measuring device is susceptible to spurious signals.

Some error measuring devices have a serious amount of high-frequency electrical noise or unfiltered ripple which tends to overload the amplifier or motor without producing any average torque. The amplification in the servo loop up to the amplifier output is a measure of the possibility of this type of overloading.

For the lead network stabilization, the high frequency amplification is proportional to

$$K_s\frac{T_A}{T_B}=\frac{J}{\tau_s^2}\times\frac{T_A}{T_B}$$
$$=\frac{J}{\tau_0^2}\times\frac{T_A}{T_B}$$

while for generator feed-back stabilization it is

$$K_s=\frac{J}{\tau_s^2}$$
$$=\frac{J}{\tau_0^2}\left(\frac{\tau_0}{\tau_s}\right)^2$$

and consequently, for equivalent static sensitivity the latter type has less gain and is superior by a factor T_B/T_A, which is less than say 0.09. However, for equivalent dynamic response they are about equal because T_A/T_B and $(\tau_0/\tau_s)^2$ are analogous.

Another type of spurious signal is a low frequency signal which cannot produce torque. For example, a signal 90 degrees out of phase from a true a-c error signal cannot produce torque in an induction motor. The gain for this type is K_s in each case so that the two are equivalent

Figure 9. Gearing design curves

on a static sensitivity basis, but the lead network type is superior on an equal dynamic response basis.

Because the error measuring device often is geared down considerably from the motor shaft, there may be a serious amount of backlash between the two which tends to promote oscillations. As the stabilizing signal in the speed feedback type is usually much more directly coupled to the motor, it has less tendency to be disturbed by the backlash of the error signal.

Motor-to-Load Gearing

In the detailed design of a servomechanism the choice of a suitable servomotor and motor-to-load gear reduction is sometimes the source of considerable confusion. An analysis of this problem leads to a means for specifying the applicability of a servomotor for a particular problem and to a procedure for finding the proper gear reduction. In addition it points out the proper direction for improved servomotor development.

The following quantities concerning the load are considered as specified by the application:

F_L = dry friction load including a safety factor
J_L = load inertia
n_L = minimum available load speed
a_L = minimum available load acceleration
e_s = allowable positional or static error due to the dry friction, as measured at the load shaft
e_a = allowable error at the load shaft due to the maximum acceleration. $\tau_a^2 \leq \frac{e_a}{a_L}$

The servomotor is characterized by

F_M = available peak motor torque
J_M = motor inertia
F_M/J_M = maximum free acceleration of the motor, or torque-to-inertia ratio
n_M = maximum speed of the motor, which is discussed in more detail later
T_M = motor response delay

The design problem may be stated as follows. Can proper gearing between the motor and load be found which will allow the servomotor to meet the application specifications?

Let g = gear reduction from the motor to the load.

The first requirement of the gearing is that the maximum motor speed after gear reduction should be not less than the required load speed

$$g = k\frac{n_M}{n_L}, \quad k \leq 1 \tag{27}$$

The second requirement is that the possible acceleration of the motor and load system be not less than a_L. The torque available for acceleration, as measured at the load shaft, is $(gF_M - F_L)$. The effective inertia at the load shaft is $(g^2J_M + J_L)$. Therefore the second condition for the gearing is

$$\frac{gF_M - F_L}{g^2J_M + J_L} \geq a_L \tag{28}$$

By combining equations 27 and 28 and arranging factors

$$\frac{F_M n_M}{(F_L + J_L a_L)n_L}\left[k - k^2\frac{a_L/n_L}{(F_M/J_M)/n_M}\right] - 1 \geq 0, \; k \leq 1 \tag{29}$$

The various factors involved in equation 29 may be given the following interpretations and symbols:

$P_M = F_M n_M$
= peak power output of the motor
$P_L = (F_L + J_L a_L)n_L$
= peak power absorbed by the load
$(A/N)_M = \frac{F_M/J_M}{n_M}$
= acceleration-to-speed ratio of the motor
$(A/N)_L = a_L/n_L$
= acceleration-to-speed ratio of the load

$$\frac{P_M}{P_L}\left[k - k^2\frac{(A/N)_L}{(A/N)_M}\right] \geq 1, \; k = g\frac{n_L}{n_M} \leq 1 \tag{30}$$

Equation 30 may be interpreted with the aid of Figure 9. For each value of $k \leq 1$, any motor which has P_M/P_L and $(A/N)_M/(A/N)_L$ values which lie to the right and above the curve for the corresponding k may be used. Thus the usefulness of a motor is determined by both P_M and $(A/N)_M$ while the difficulty of a set of specifications is measured by P_L and $(A/N)_L$.

Equation 30 may be placed in another form which shows up other aspects of these relations. Thus

$$\frac{P_M}{P_L} \times \frac{(A/N)_M}{(A/N)_L}\left[\frac{k}{\frac{(A/N)_M}{(A/N)_L}} - \left(\frac{k}{\frac{(A/N)_M}{(A/N)_L}}\right)^2\right] \geq 1 \tag{31}$$

Equation 31 has a solution only if

$$\frac{P_M}{P_L} \times \frac{(A/N)_M}{(A/N)_L} \geq 4 \tag{32}$$

Figure 10 illustrates these relations. In view of equation 32 it appears that

$$P_M \times (A/N)_M = F_M^2/J_M$$

is another measure of the usefulness of a motor, and

$$P_L \times (A/N)_L = (F_L + J_L a_L)a_L$$

is a measure of the specification difficulty. Thus a high value for F_M^2/J_M appears to be more valuable for a motor than a high value for the usually specified torque-to-inertia ratio F_M/J_M.

The justification for placing these equations in such a difficult form is that any measure of the performance of a motor must be independent of any gearing placed after the motor. Thus $P_M = F_M n_M$, $(A/N)_M = F_M/J_M n_M$, and F_M^2/J_M are all independent of gearing. A motor disguised by the addition of a gear box is still the same motor and has the same range of application. This is not true for the torque-to-inertia ratio specification.

In addition to its power and acceleration-to-speed ratio, the merit of a motor is measured also by its response delay T_M. For the two types of servomechanism under discussion, T_M must be less than about $0.25\tau_a$, where τ_a is determined by the specifications according to the following relations:

$$\tau_a^2 \leq e_a/a_L \tag{33}$$

Figure 10. Gearing design curves

Figure 11. Torque–speed characteristic

$$16T_M^2 \leq \tau_a^2 = \tau_s^2 \text{ for lead network stabilization} \quad (34)$$

$$16\Gamma_M^2 \leq \tau_a^2 = (11 \text{ to, say, } 40)\tau_s^2 \text{ for speed feed-back stabilization}$$

and

$$\tau_s^2 = \frac{J}{K_s} \leq \frac{J_M k^2 + J_L}{F_L} \times e_s$$

$$= \frac{k^2 J_M n_M^3 + J_L n_L^3}{F_L n_L^2} \times e_s \quad (35)$$

If the specifications should call for a τ_a^2 according to equation 33 which is too small relative to T_M^2, there is no choice but to find a new motor with less delay. If, however, it is the specifications according to equations 34 and 35 which are difficult to meet, τ_s^2 may be kept large by setting k as near unity as possible. Another possibility is to add to the motor inertia J_M, provided only that equation 33 is not violated and that $(A/N)_M$ is not reduced too far to make gearing impossible.

A numerical example can illustrate these relations more clearly. Consider the following set of specifications:

$F_L = 5{,}000$ inch-ounces
$J_L = 2{,}000$ inch-ounces per radian per second^2
$a_L = 0.5$ radian per second^2
$n_L = 0.5$ radian per second
$e_a = 0.001$ radian
$e_s = 0.0005$ radian

These specifications determine

$$P_L = (F_L + J_L a_L) n_L$$
$$= (5{,}000 + 2{,}000 \times 0.5)(0.5)$$
$$= 3{,}000 \text{ inch-ounce-radians per second}$$

$$J_L n_L^2 = 2{,}000 \times (0.5)^2$$
$$= 500 \text{ inch-ounce-radians}$$

$$e_a/a_L = \frac{0.001}{0.5}$$
$$= 0.002 \text{ second}^2$$

$$(A/N)_L = a_L/n_L$$
$$= \frac{0.5}{0.5}$$
$$= 1 \text{ per second}$$

These values determine that the motor chosen must have a power at least as large as P_L and a delay T_M less than

$$0.25\sqrt{e_a/a_L} = 0.25\sqrt{0.002}$$
$$= 0.011 \text{ second}$$

Consider a motor with the following characteristics:

$F_M = 10$ inch-ounces
$J_M = 0.002$ inch-ounce per radian per second^2
$n_M = 500$ radians per second
$T_M = 0.01$ second

Then

$$P_M = F_M n_M$$
$$= 10 \times 500$$
$$= 5{,}000 \text{ inch-ounce-radians per second}$$

$$F_M/J_M = \frac{10}{0.002}$$
$$= 5{,}000 \text{ radians per second}^2$$

$$(A/N)_M = \frac{5{,}000}{500}$$
$$= 10 \text{ per second}$$

$$J_M n_M^2 = \frac{5{,}000}{10}$$
$$= 500 \text{ inch-ounce-radians}$$

Therefore

$$P_M/P_L = \frac{5{,}000}{3{,}000}$$
$$= 1.67$$

$$\frac{(A/N)_M}{(A/N)_L} = \frac{10}{1} = 10$$

$$\frac{n_M}{n_L} = \frac{500}{0.5} = 1{,}000$$

Referring these values to Figure 9 indicates that k may be between 1 and 0.64, so that the gearing may be between 1,000 and 640. With these values τ_s^2 may be calculated according to equation 35

$$\tau_s^2 = \frac{k^2 500 + 500}{5{,}000 \times (0.5)^2} \times 0.0005$$
$$= 0.0004 \text{ second}^2 \text{ for } k = 1$$

Thus τ_s may be 0.02 second or somewhat less.

If the lead network type of stabilization is used, $\tau_a = \tau_s = \tau_e$ and each must be greater than $4T_M = 0.04$ second. Therefore, something must be done about increasing τ_s from 0.02 to 0.04. One possibility which often works is to increase J_M by the addition of extra inertia.

With the power ratio $P_M/P_L = 5/3$, the acceleration-to-speed ratio may be decreased to 2.4 (from Figure 9) and still allow a gearing solution $k = 1$. Then

$$\tau_s^2 = \frac{1 \times \frac{5{,}000}{2.4} + 500}{5{,}000 \times (0.5)^2} \times 0.0005$$
$$\approx 0.001$$

$\tau_s \approx 0\ 032$, which is still too small, but J_M cannot be increased further without more motor power.

Consequently, in order to use the lead network stabilization, a motor with less delay must be found or some of the specifications relaxed, possibly by allowing the slightly higher resonance obtained with

$$T_M/\tau_e = \frac{0.01}{0.032} = 0.32$$

In this case the resonance peak is still less than 1.5.

For the speed feed-back type of stabilization, $\tau_a^2 = \tau_e^2$ is limited fairly closely to 0.002 second^2 as it cannot be larger and meet the specifications nor can it be much smaller and still have $\tau_e > 4T_M$. Therefore, τ_s^2 must be less than about $(1/11)\tau_e^2 \approx 0.00018$ second^2. τ_s^2 may be made smaller either by reducing the gear ratio or by setting the value of e_s lower, that is, by increasing K_s. If k is set at its minimum value $k = 0.64$

$$\tau_s^2 = \frac{(0.64)^2 500 + 500}{5{,}000(0.5)^2} \times 0.0005$$
$$= 0.00028 \text{ second}^2$$

τ_s^2 is still too large so that the value of e_s must be decreased, that is, the sensitivity

$$K_s = F_L/e_s$$

must be greater than the static specifications require. But this is no disadvantage except possibly that a less noisy error signal is required.

Motor Torque–Speed Characteristics

Thus far in the analysis a critical discussion of what is meant by peak motor speed n_M has been avoided. The assumption has been made that the motor torque for full excitation is reasonably constant up to a limiting speed n_M. There are several motor types for which this assumption is good; for instance, certain induction motors which have fairly constant torque up to the region of synchronous speed. A-c and d-c motors in which the field is controlled by vacuum tubes and the armature circuit is arranged to keep the current fairly constant and independent of the back electromotive force are also in this class. In the latter case there is either a speed above which it is not considered mechanically feasible to drive the motor or a speed at which the torque falls off fairly sharply because of a rapid increase in windage and hysteresis losses, or a change in circuit conditions.

Other electric motors such as certain induction motors and d-c motors which have their armature voltage controlled

have a torque characteristic which falls off more or less linearly with speed over the useable range, as shown in Figure 11. In this case the analysis is more complicated because there is an error proportional to speed in addition to the static and acceleration errors which must be specified. In forming specifications for a system using a motor of this type, it is necessary to consider such things as what proportions of maximum speed and maximum acceleration are likely to occur simultaneously and whether or not it is allowable to have larger errors at high speed than at low speed.

If the same forward accelerations are desired at all speeds, the problem is somewhat simplified as n_M may be chosen at any value which will give

$$P_M = (F_M - \Delta F_M) n_M$$

and

$$(A/N)_M = \frac{F_M - \Delta F_M}{J_M n_M}$$

values which allow a gearing solution. As both P_M and $(A/N)_M$ decrease with speed, there is a maximum allowable speed n_M which falls on the portion of the curve of equation 30 for $k=1$.

The damping factor f/J used previously for the complete system is

$$\left(\frac{\Delta F_L}{J_L n_L} + \frac{\Delta F_M}{J_M n_M}\right) \text{ second}^{-1}$$

where ΔF_L is the increase in load from zero speed to speed n_L, and ΔF_M is the decrease in motor torque from zero speed to speed n_M. Both factors have the dimension of second^{-1} and may be added directly without the introduction of gear ratios. $\Delta F_M / J_M n_M$ will be always less than

$$\frac{F_M}{J_M n_M} = (A/N)_M$$

and for many cases will be only one-half this value, corresponding to maximum motor power output at speed n_M.

In the absence of a definite application, it does not appear worth while to pursue this analysis further. There is one important class of applications, namely, instrument servomechanisms, to which the gearing analysis does not completely apply as both F_L and J_L are considered negligible, but the same principles should apply.

Other Servomechanism Types

There are several other types of servomechanisms with different physical equipment to which the same basic equations or small variations apply. Some of these will be described briefly.

It has been assumed that the principal delay was in the motor, but the analysis will apply as well to any other equipment with a delay in the same portion of the control loop as the motor.

A form of stabilization similar to lead network stabilization may be obtained if some speed measuring device is placed on both the input and output shafts and the difference in speed $(px_i - px_o)$, which is equal to the error derivative pe, added to the error signal yielding a signal $(1+T_A p)e$. In this case T_B may be taken equal to zero or considered as a secondary delay.

In place of a generator with a high-pass filter producing a signal

$$\frac{T_G T_N p^2}{1+T_N p} x_o$$

it is possible to use an accelerometer with a low-pass filter or a delay network yielding

$$\frac{\tau_a^2 p^2}{1+T_N p} x_o .$$

The same analysis applies, but variation of any of the physical parameters has a different effect on the analysis parameters τ_s, τ_o, T_N/τ_o, and so forth, than previously. The extension is fairly straightforward.

If an inertia J_D is coupled to the servomotor by viscous friction with coefficient f_D, a device known as an inertia damper is obtained. Oil often is used for the viscous coupling so that the torque on the damper inertia is proportional to the difference in speed of the motor and damper. Analysis of this case yields

$$\frac{\text{Motor torque}}{x_o} = p^2 J \left[\frac{J+J_D}{J}\right] \times \left[\frac{1+p\dfrac{1}{f_D} \times \dfrac{JJ_D}{J+J_D}}{1+p\dfrac{J_D}{f_D}}\right] \quad (36)$$

where all quantities are measured at the load shaft, that is, $J = J_L + g^2 J_M$, $J_D = g^2$ (damper inertia), and $f_D = g$ (friction coefficient).

This inverse transfer function is similar to the square bracket of equation 18 and the following analogous relations may be set up:

$$\tau_s^2 \longrightarrow J/K_s$$

$$\tau_a^2 = \tau_o^2 \longrightarrow \frac{J+J_D}{K_s}$$

$$(\tau_s/\tau_o)^2 \longrightarrow \frac{J}{J+J_D}$$

$$T_N \longrightarrow J_D/f_D$$

$$T_G \longrightarrow f_D/K_s$$

and analogous design relations apply. It is interesting that this servomechanism is similar to the speed feed-back type when $T_M = 0$, and $\tau_s^2 \neq \tau_o^2$. However, all delays have an effect similar to that for the lead network type, and in particular, the extreme sensitivity to secondary delays is not present.

Other types have transfer functions different in algebraic form from those given but closely approaching the same form for values of λ greater than some small value, say, 0.5. For these, some of the same design criteria may be used, along with additional ones which allow the various types to converge for $\lambda > 0.5$. Examples of this type are the commonly known integral controls which are best left to a separate paper.

Appendix. Nomenclature

a_L = minimum available load acceleration

$(A/N)_M = \dfrac{F_M/J_M}{n_M}$ = acceleration-to-speed ratio of the motor

$(A/N)_L = a_L/n_L$ = acceleration-to-speed ratio of the load

c = ratio of secondary-to-primary delay

$e = x_i - x_o$ = deviation or error

e_a = allowable error at the load shaft due to the maximum acceleration

e_s = allowable proportional or static error due to dry friction, as measured at the load shaft

F = dry friction torque

f = viscous friction coefficient or torque change per unit change of speed

F_L = dry friction load torque including a safety factor

F_M = available peak motor torque

F_M/J_M = maximum free acceleration of the motor, or torque-to-inertia ratio

g = gear reduction from the motor to the load

J = effective moment of inertia of motor and load

J_L = moment of inertia of the load

J_M = moment of inertia of the motor

K_s = motor torque per unit error, static sensitivity

λ = nondimensional measure of angular frequency

n_L = minimum available load speed

n_M = maximum motor speed

p = differential operator

$P_L = (F_L + J_L a_L) n_L$ = peak power absorbed by the load

$P_M = F_M n_M$ = peak power output of the motor

T_A = circuit time constant

T_B = circuit time constant

T_G = circuit time constant

T_N = circuit time constant

T_M = motor response delay time

$\tau_a = \sqrt{\dfrac{\text{acceleration error}}{\text{acceleration}}}$, a time constant

$\tau_s = \sqrt{J/K_s}$, a defined time constant

$\tau_p = \lambda/\omega$, servo time constant used as a measure for other time constants

x_i = input co-ordinate

x_o = output co-ordinate

Discussion

H. Chestnut (General Electric Company, Schenectady, N. Y.): In the design of servomechanisms, there are employed two basic methods of providing the desired stability and accuracy of an over-all system or for components within a system. In this paper, Herbert Harris points out examples of these basic methods as applied to a torque motor power element with an associated time constant. As is indicated so ably by Harris, the two methods when properly employed produce quite comparable results in many respects. I should like to generalize further the two basic design methods and point out some applications where one or the other method is particularly well fitted. The basic design methods to which I refer have been termed

1. Series means for providing stability and accuracy.

2. Feedback or parallel[1] means for providing stability and accuracy.

These are illustrated by the examples shown in Figures 1 and 2 respectively of Harris' paper. In many high performance servomechanisms both of these means are employed, each being used to provide their desired effect. The automatic control system shown in Figure 3 of George J. Schwartz's paper[2] is illustrative of a servomechanism system in which both series and feed-back stabilizing means are employed.

When series methods are employed, the stabilization is inserted in series with the remainder of the system, and compensation is made for the characteristics of the remainder of the system. As long as the characteristics of the remainder of the parameters of the system are constant and do not vary appreciably with time or operating conditions, the series method may be employed to advantage.

However, if, for example, the gain of the motor K_s were to change, the values of $\tau_s = \tau_o$ and T_m/τ_o would change; as the design values listed in Harris' paper are based on a certain T_m/τ_o ratio, the change in gain will alter the performance of the system directly.

In cases where there are a minimum of spurious higher frequency signals present in the input, this method is advantageous. As pointed out by Harris, these spurious signals may overload amplifier and prevent proper amplification of desired signals. In addition to the use of lead network of the type illustrated in the example used by Harris, series means may include lag networks which decrease the signal transmitted through them at higher frequencies rather than increase them as in the case of lead networks. So-called "integral type" controllers fall into this category. Frequently, combinations of lead and lag networks are used to produce different desired effects in the various frequency ranges included in the input signal to the servomechanism.

The use of cheap reliable network elements in the amplifier stages of a servo amplifier is particularly attractive in that little added equipment or maintenance is required when these series means are employed. However, changes in the gain of the remainder of the system, which generally occur with time, if not with operating conditions, are not mitigated at all by the series stabilizing means. Hence, in large production jobs, where close manufacturing tolerance can be obtained only at additional expense, series stabilization seldom is used exclusively.

Feed-back means are used to provide a net signal to a servo element which is a function of the input to that element and some function of the output of the element. In a sense it is a supplementary closed loop and its performance and stability must be considered in the same careful manner that the over-all closed loop is considered. Three desirable functions which feed-back means can be made to perform are the following:

1. Feedback can minimize the effect of changing gain of an element on the stability and dynamic accuracy of a system.

2. Feedback can be used to reduce the time constant of a servoelement.

3. Feedback can be used to modify the form of a servoelement.

Harris' summary of design information pertaining to the feed-back type of servomechanism illustrates the first point. The

Figure 1. Servo element

Figure 2. Servo element (top) and feed-back element (bottom)

delay limitation is shown to be imposed by the T_m/τ_o ratio where

$$\tau_o^2 = \tau_s^2 + T_G T_N$$

$$\tau_s^2 = J/K_s$$

$T_G T_N$ is determined by the feed-back parameters.

For good design $T_G T_N$ is shown to be much greater than τ_s^2, greater than nine to one in the illustrative example. Hence changes in τ_s caused by changes in gain K_s represent a smaller percentage change in τ_o and likewise in T_m/τ_o ratio. The feed-back parameters $T_G T_N$ are the dominant factors, and they are quantities which are selected at the discretion of the designer.

Noting that the time lag for constant acceleration output motion is $(\tau_s^2 + T_G T_N)$ times the acceleration, it is apparent that changes in τ_s^2 caused by changes in the gain K_s will not be noticeable because of the high ratio of $T_G T_N$ to τ_s^2. Hence the use of feed-back has reduced the change in the over-all accuracy for high acceleration signals caused by the changes in the gain of the servomotor itself.

Although use has been made of the results of Harris' work on a specific system, a more generalized analysis of feedback reveals the same beneficial results of feedback.

To illustrate the use of feedback in reducing the time constant of a servo element consider Figure 1 of this discussion. A servo element with gain K and a time constant T_1 is shown by the solid lines. The input to the element is E_{in}, the output E_o. Thus

$$\frac{E_o}{E_{in}} = \frac{K}{1+T_1 p}$$

If now the output is fed back to the input as shown by the dotted line, the following equation for the system may be written:

$$\frac{K(E_{in} - E_o)}{1+T_1 p} = E_o$$

Combining

$$KE_{in} = (T_1 p + 1 + K)E_o$$

and finally,

$$\frac{E_o}{E_{in}} = \frac{K}{1+K}\left[\frac{1}{1+\frac{T_1}{1+K}p}\right]$$

Thus the time constant T_1 has been reduced effectively to $\frac{T_1}{1+K}$ by the use of feedback. Because, as is pointed out in Harris paper, the limit on servomechanism performance frequently is caused the value of a

particular time constant, feedback provides a means for reducing the offender.

However, it will be noted that there has been a loss of gain by the same $\frac{1}{1+K}$ factor which must be compensated for elsewhere in the system. Generally amplification can be obtained at low power levels and this is no severe limitation.

Modification of the form of a servoelement is an important application of feedback and Figure 2 of this discussion should serve to illustrate this point. The servoelement shown in solid lines, with input E_{in} and output E_o, has a transfer function.

$$\frac{E_o}{E_{in}} = \frac{K}{p^3}$$

Suppose now the output is fed back through a feed-back element shown by the dotted connection which has as its transfer function

$$\frac{E_f}{E_o} = K_s p$$

The resultant equation for the system with the feedback connected is

$$\frac{E_o}{E_{in}} = \frac{1}{K_s p\left(1+\frac{p}{KK_s}\right)}$$

If $KK_s \gg 1$, then this equation reduces to

$$\frac{E_o}{E_{in}} = \frac{1}{K_s p}$$

and the transfer function has been changed in form from one in which the output acceleration is proportional to the input signal to one in which the output is proportional to the input signal.

As Harris has pointed out, the feed-back signals can be used most effectively when they are used with filters which utilize the feed-back effect only over a limited portion of the frequency range.

Although the use of feedback presents many attractive features, it is important not to gloss over some undesirable items associated with its use. In many cases tachometers or other signal sources are required which add cost and weight and increase the problems of production and maintenance. Frequently, additional wiring is required to bring the feed-back quantities into the amplifier stages. Occasionally, cathode followers, isolating amplifiers, or other means are required to change impedance levels and prevent undesirable interaction of elements. These factors, though not appearing explicitly in the technical analysis, nevertheless figure very prominently in the complete engineering appraisal of a servomechanism system.

Utilizing the concepts of series and feedback methods of stabilization, and using the attenuation-phase shift method described by Mac Coll,[3] one realizes that the use of single *RC* networks has limited somewhat the performance which can be obtained from the servomotor. By employing, on a series basis, two stages of lead networks or the equivalent and providing added gain, the static accuracy and frequency response can be improved. Likewise, by employing two stages of the *RC* network used in the feed-back network and appropriately changing the values of T_N, T_G, and K_s, an improved system utilizing feedback can be obtained. The complexity in analysis required by these added terms would contribute little to the comparison of the two basic servomechanism types performed so capably by Harris. I mention them only as possible means for overcoming some of the design limitations which are dependent on the filter characteristics which are assumed.

In conclusion I should like to take notice of the choice of $M=1.25$ as a design criterion for satisfactory performance. This figure seems to be somewhat lower than generally is considered essential for a system with satisfactory performance. In an actual system, the use of a lower M figure than is necessary means that the speed of response of the system may be impaired or a more elegant and costly design must be employed.

H. Tyler Marcy (M. W. Kellogg Company, Jersey City, N. J.): Herbert Harris is to be congratulated for undertaking a direct comparison of two servomechanism types often proposed for the same function.

I should like to indicate another interpretation of two of Harris' equations (8 and 13) which leads more easily to a comparison of the two techniques. If a nondimensional operator γ be defined as $T_M p$ then equations 8 and 13 may be rewritten.

$$\frac{e}{X_e}\frac{K_s T_M^3}{J} = \gamma^3(1+\gamma)\frac{1+\frac{T_B}{T_M}\gamma}{1+\frac{T_A}{T_M}\gamma}$$

$$\frac{e}{X_e}\frac{K_s T_M^3}{J} = \gamma^3(1+\gamma)+\frac{\frac{T_N T_G K_s}{J}\gamma^3}{\left(1+\frac{T_N}{T_M}\gamma\right)}$$

$$= \gamma^3(1+\gamma)\left[1+\frac{\frac{T_N T_G K_s}{J}}{(1+\gamma)\left(1+\frac{T_N}{T_M}\gamma\right)}\right]$$

For the two systems to be nearly alike in resonant characteristics, which has been used as a criterion of similarity, then the comparison of the two techniques reduces to a comparison of the two functions.

$$\frac{J}{K_s T_M^3}\frac{1+\frac{T_B}{T_M}\gamma}{1+\frac{T_A}{T_M}\gamma} \qquad (1)$$

Figure 3

and

$$\frac{J}{K_s T_M^3}\frac{\frac{T_N}{T_M}\gamma^3+\left(\frac{T_N}{T_M}+1\right)\gamma+\left(1+\frac{T_N T_G K_s}{J}\right)}{\frac{T_N}{T_M}\gamma^3+\left(\frac{T_N}{T_M}+1\right)\gamma+1} \qquad (2)$$

Both these functions are familiar when the operator γ is replaced by a complex frequency $j\omega$ and loci drawn. The first is the reciprocal of a lead network and is a semicircle. The second is a form of a matching lead network discussed by Hall.[1] Figure 3 of this discussion shows sketches made of these loci when $J/K_s T_M^3=1$ and an attenuation ratio of five assumed for the lead network.

It will be recognized that there is more freedom in the design of the tachometer feedback as represented by loci for matching lead networks. It at once will be obvious that the two loci can be made to approximate the same phase characteristic over a critical frequency range. This can be done with an increase of the system K_s if an adequate signal level is available from the tachometer as Harris points out.

Herbert Harris: The discussions of H. Chestnut and H. Tyler Marcy are quite constructive, and the author has no real disagreement with any of the points presented. Personal preferences as to methods of analysis and to specifications, such as allowable height of resonance peaks, always will be present as long as engineers work in different organizations and on different equipment.

The author wonders whether Chestnut can have any proof of his generalization that feed-back means of stabilization is always less susceptible to the efforts of parameter changes than the series method. These two cases do not prove such a generalization, and it would seem possible to devise contradictions.

The apparent cheapness of network components is often spurious whenever feedback means of stabilization can allow the mechanical system to have less rigidity and more backlash.

An Integrated Control System for Aircraft D-C Generators

A. T. McCLINTON
ASSOCIATE AIEE

Synopsis: This paper describes an electric system for d-c generators used on aircraft that allows physical integration of all control elements normally associated with the control of the generator. The proposed system differs from the present system used by the Army and Navy primarily in that integration has been accomplished in addition to offering automatic control of the generator without a sacrifice in system performance. No attempt has been made to compare this system with present systems. It is the purpose of this paper to describe the individual control elements of the proposed system and to discuss their characteristics.

THE OUTPUT of d-c generators in use at the present time in aircraft is controlled primarily by two elements, namely, a regulator and a relay. The function of the regulator is to maintain the voltage at a predetermined magnitude at some particular point on the electric system for specific conditions of operation of the generator. The principal function of the generator control relay is to connect the generator to the bus whenever the generator is capable of furnishing power to the bus and to disconnect the generator when it is no longer able to furnish power. Controlling this relay by a switch provides a means for manually disconnecting the generator from the bus. Other items normally associated with these control elements are a voltmeter, ammeter, a visual indicator to signal when the generator is disconnected from the bus, and some provision for connecting the equalizer coil to the equalizer bus.

If proper consideration is given to the selection of these control elements and to the configuration of the generator control system, it should be possible to realize the following:

1. System regulation at the aircraft load bus should not be dependent upon the regulator characteristic and line drop but should be governed simply and effectively for any system.

2. Load division should be controlled accurately and readily and should not be dependent upon the proper balance of line resistances and regulator characteristics.

3. The operation of each generator, whether on a single or multigenerator system, should be automatic, thus requiring none of the pilot's or flight engineer's attention.

4. The design and arrangement of the various control elements should permit placing all of these elements into one control panel (in all present installations these generator control elements appear in the aircraft as separate units and frequently in widely spaced parts of the aircraft), so that

(a). Servicing of the aircraft would be simplified.
(b). Possible faults in the control circuit can be determined readily and corrected.
(c). Setting of system voltage would be simplified.

5. The control system would allow bench adjustment of all components. The only adjustment necessary after the control unit is placed in the aircraft would be to set the system voltage.

This, by means of introduction, defines the requirements which the generator control system should meet. In order to satisfy these requirements for system performance, the control elements have been set up as follows.

Voltage Regulator

In order to accomplish the first two requirements for the control system, the voltage regulator should be able to maintain the same no-load voltage for all generators as well as to give approximately the same regulation for each generator comprising the system. If it were possible to obtain identical regulation for all generators, the problem of obtaining proper load division would be simplified greatly. Experience has demonstrated, however, that with present carbon pile regulators the regulation is dependent upon the setting of the regulator as well as upon the particular generator used. One other factor which must be considered is the voltage drop in the power leads from the point of regulation to the point of paralleling the generators.

As a means of providing uniform regulation which is independent of these factors, it is proposed that a carbon pile regulator, equipped with a line-drop compensating coil be used. Such a device was used formerly on the industrial Tirrel-type regulator. Figure 1 shows a schematic diagram of this regulator with the connections to the generator. The voltage signal for the line-drop compensating coil is taken from a potentiometer which is connected across the series field of the generator. Because the drop across the series field is proportional to the generator current, the resultant effect of the line-drop compensating coil on the regulated voltage will be proportional to the generator current. The connections to the potentiometers will allow for either plus or minus compensation; that is, the voltage at the load bus can be made to increase or to decrease with increase in generator current. Thus the regulation of the electric system can be made drooping, flat, or rising; but of greater importance, it can be controlled. This

Paper 47-14, recommended by the AIEE committee on air transportation for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted October 11, 1946; made available for printing November 7, 1946.

The author acknowledges the work of J. W. Allen, bureau of aeronautics, Navy Department, Washington, D. C., in the development of the line-drop compensating coil for the carbon pile regulator used on aircraft.

satisfies the first system-control requirement.

The second requirement of the control system is met by the equalizer coil. In addition to the line-drop compensating coil and voltage coil, each regulator is provided with an equalizer coil which is wound in a direction such as to compensate for unbalanced loads between generators. This coil has an amplification factor of approximately ten; that is, 0.25 volt across the equalizer coil will produce a 2.5-volt change in regulated voltage. Equalizer potential is obtained by using part of the voltage drop across the generator series field. An equalizer potentiometer, connected as shown in Figure 1, is used for this. Through the use of this potentiometer it is possible to adjust the equalizer potential to the same value for all generators. The resistance of the grounding circuit (bolts, lugs, and contacts) as well as lead resistance are neutralized through the use of the equalizer potentiometer.

As the regulation of each generator on a system can be controlled by means of the line-drop compensating coil, the setting of the equalizer potentiometer is independent of voltage regulation and thus can be made the same for all regulators on a system. The potentiometer is set to give a potential from tap to ground equal to 1.6 volts at full load on the generator. A voltage of 1.6 volts was chosen rather than some lower voltage because of the fact that better load division results. Because this voltage is compared with a similar voltage on other regulators connected to the equalizer bus, the error signal, for a given percentage load unbalance, is going to be proportional to the total drop across the equalizer potentiometer. It necessarily follows then that if the drop across the equalizer potentiometer is set for 1.6 volts rather than 0.8 volt, the minimum load unbalance detected by the regulator in the system using 1.6 volts will be one-half that of the system using 0.8 volt drop. Thus, better load division will result from the system using the higher equalizing voltage. The magnitude of equalizer potential was limited to 1.6 volts by the fact that the voltage drop across the series field of present standard aircraft generators varies from 1.6 volts to 5.0 volts, and it is desirable to standardize on one voltage setting for all generators.

The selection of an equalizer voltage of 1.6 volts coupled with the high amplification of this equalizer circuit necessitates the removal of this coil from the equalizer bus when the associated generator is disconnected from the load bus.

Equalizer Circuit

In an effort to illustrate the effect of the equalizer coil on bus voltage when the associated generator is disconnected from the bus, Table I is presented. This table, based on an equalizer circuit resistance of 2.0 ohms does not represent the worst possible condition of operation, but demonstrates what is found to be the case in a typical system.

From this it becomes evident that the equalizer coil must be disconnected from its bus when the generator is disconnected

Figure 1. Schematic diagram of the voltage regulator control unit

Table I

Number of Generators in the System	Number of Generators Disconnected From Bus	Decrease in Bus Voltage With Full Load on Remaining Generators*
2	1	3.3
4	1	1.65
4	2	3.3
4	3	4.95

*This is based on the use of equalizer coils in which 0.25 volt causes a 2.5-volt change in regulated voltage; the equalizer potentiometer is set for 1.6 volts at full generator load; the equalizer circuit resistance is considered to be 2.0 ohms (0.4 ohm for each equalizer coil plus 1.2 ohms for interconnections).

Figure 4. Closing characteristic of pilot relay when used with the integrated control system

Figure 5. Characteristic of regulator equalizer coils and generator control elements on a multigenerator system

from the load bus. In the proposed system this was accomplished by inserting a relay in the equalizer circuit and connecting its operating coil between the armature of the double-break line contactor and ground (Figure 2). Thus, when the line contactor is open, the equalizer control relay is de-energized. The reasons for using this circuit in preference to several other possibilities will be evident as the complete integrated control system is developed.

Figure 2 immediately brings up another element used for generator control, that is the pilot relay which controls the line contactor.

Pilot Relay

This important item in the control system connects the bus to the generator when it can carry load, and disconnects the generator when it will no longer carry load. The pilot relay developed for use with the proposed system is a polarized device having two identical voltage coils and one current coil. The relay operates on a differential voltage principle, the two voltage coils giving the signal for closing, and the current coil giving the signal for opening the relay on reverse currents. Connections for this relay are shown in Figure 3. Referring to Figure 3, the line contactor coil is energized through the contacts of the pilot relay and a manually operated switch. Coil 2 or 3 will close the relay when the voltage across either coil is at least 0.4 volt and of the proper polarity, or when the algebraic sum of the coil voltages is at least 0.4 volt. Coil 1 will open the relay when no less than 0.08 volt of the proper polarity is impressed across the coil. The generator switch has been inserted to make it possible to remove the generator from the load bus. Referring to Figure 3, it will be noted that one of the voltage coils of the pilot relay connects across the contacts of the equalizer relay, completing the circuit for the equalizer coil to the equalizer bus. Because the load differential coil has a resistance of 20 ohms, the current in the equalizer coil circuit cannot decrease the bus voltage by more than 0.2 volt. This small change in bus voltage resulting from the pilot relay is of negligible magnitude.

The operation of the pilot relay is as follows. (This discussion is based on a 2-generator system although it can be made to apply for any number of generators.) Assume that the equalizer resistors are adjusted for 1.6-volt drop at full load on the generator and that one generator is connected to the bus. When the system load is zero, the voltage from the equalizer bus to ground or across the equalizer relay of the generator off the bus will be zero. Thus, the pilot relay can close only when the voltage of the oncoming generator is at least 0.4 volt higher than the bus voltage. If the system load is one-fourth rated generator load, the voltage from equalizer bus to ground is 0.4 volt. Under this condition the pilot relay will close as long as the generator voltage is at least equal to the bus voltage.

As a further explanation of the operation of this relay, its closing characteristics are plotted in Figure 4. Curve *B* shows the closing characteristic of the pilot relay when only coil 3 is employed. The relay pickup tolerance is approximately plus or minus 0.1 volt which gives the band from 0.3 to 0.5 volt shown on the curve. It should be noted that the

pickup characteristic of this coil is independent of the load on the aircraft bus. When coil 2 is connected also, the characteristic of the pilot relay is dependent upon the system load. The voltage across coil 2 is the same as the voltage drop from ground to equalizer bus, which is shown by curve *A*. As the flux created by the two coils adds algebraically to close the pilot relay, and because coils 2 and 3 are identical, the voltage differential between the oncoming generator and the bus need not be plus 0.4 volt but can be some value less, the amount depending upon the bus load. Because the algebraic sum of the voltages across these coils must be plus 0.4 volt, we need only to subtract the value of voltage appearing across coil 2 from 0.4 volt to get the voltage differential between the oncoming generator and bus which will allow closure of the pilot relay. This is done on Figure 4 by subtracting curve *A* from curve *B* to give the resulting closing characteristic, curve *C*.

The fact that the oncoming generator can have a voltage lower than the bus voltage at the time it is connected to the line brings up the question as to how this generator will be able to carry any of the system load. This is accomplished through the action of the equalizer coils. In way of explanation, let it be assumed that the equalizer coil of a generator is connected to the equalizer bus, but the line contactor of this generator is open. If there is a load on the remaining generators connected to the bus, the current flow in the equalizer circuit will cause an increase in voltage of the generator off the bus (line contactor open) and will cause the voltage of all generators on the bus to decrease. This will result in a new value of voltage difference between the generator off the bus and the bus voltage. The magnitude of this voltage differential caused by action of the equalizer coils is shown in Figure 5. This voltage difference is independent of the number of generators making up the system and the number of generators disconnected from the load bus. As long as the equalizer coils are able to produce a voltage differential which is numerically greater than the values on curve *C*, Figure 4 for corresponding bus load, the oncoming generator will take part of the bus load. A comparison of these curves will reveal that the slope of curve *C* can be increased greatly and still meet these requirements. An increase in the slope of this curve might be desirable in view of the fact that if the increase were accomplished a generator could be paralleled with the bus at lower system loads for a given voltage difference between the oncoming generator and the bus. This can be accomplished by increasing the ampere turns of coil 2, Figure 2; doubling it would double the slope of this curve.

The action of coil 1, Figure 3, is to open the pilot relay on reverse currents; that is, when the generator is no longer capable of carrying load. This coil will open the pilot relay when the voltage drop from the tap on the equalizer to ground is 0.08 volt. As the equalizer potentiometers are adjusted for 1.6 volts at full load on the generator, the pilot relay will open on a generator reverse current equal to five-per-cent rated generator current.

Control Unit

The required generator control unit, as shown on Figure 3, now consists of the

Figure 6A. Load division characteristics of a 2-generator system

Figure 6B. System voltage characteristics of a 2-generator system

aforesaid voltage regulator, pilot relay, and equalizer control relay in addition to a combination voltmeter and ammeter, a generator switch, an indicator lamp for signaling when the generator is disconnected from the load bus, and pin jacks.

These elements are mounted in one box which can be mounted in the control panel of the aircraft. The ballast lamp is inserted in series with the voltage differential coil to protect this sensitive coil from high reverse voltages. The 50-millivolt shunt and the line contactor are located externally to the control unit to avoid the necessity of having to run the generator current through the control unit.

Load Division

To demonstrate the capabilities of the proposed system to divide the load properly between generators, several tests were made involving different values of line resistance and different size generators. The tests showed that good division would result from the use of this system of parallel operation. Figures 6*A* and 6*B* show results which are typical of a system employing this control unit, where the bus voltage has been adjusted to rise with increase in load. The positive line resistance from each generator to bus was 0.045 ohm and 0.07 ohm, respectively. Ground circuit resistance was approximately 0.001 ohm. The regulator voltage coils were connected to the positive terminal of the generator.

Conclusions

In view of the many operational problems resulting from the use of several individual items of control equipment for aircraft generators, it is desirable that an integrated control system be adopted. It is believed that by the indicated selection and arrangement of control items, a unified system can be constructed which will result in the following:

1. Simplified maintenance problems because of the provision for quick removal of the control elements for bench adjustment.
2. Improved operation arising from a system kept in better adjustment.
3. Reduction in weight and space requirements over that required with decentralized location of devices.

The control system proposed demonstrates that it is possible to build a control unit for aircraft generators that makes the following attainable:

1. Accurate control of the bus voltage by means of control of the system regulation. It is not necessary to rely upon proper regulator adjustment, use of certain generators, or accurately determined line drops.
2. Connection of the bus to the generator when, and only when, it can furnish power to the bus.
3. An automatic system.
4. Better division of load.

No Discussion

The Calibration of Ignition Crest Voltmeters

W. L. DAVIS
MEMBER AIEE

C. E. WARREN
ASSOCIATE AIEE

IN STUDYING the performance of aircraft and automotive types of internal combustion engine ignition systems, ignition crest voltmeters have been used for the measurement of peak voltages at various points in the systems. Several types of meters have been developed for this purpose. Field experience with these meters has shown a considerable variation in reading between the several meters when connected to the same point in the ignition system. In view of the inconsistent performance of the meters, a study was undertaken in which several of the factors influencing the performance of the various available voltmeters were segregated and analyzed separately.

Fundamental Considerations

One of the first factors to be considered in the study of performance of crest voltmeters was the wave shape of the voltages to be measured. Oscillographic records of voltages encountered in both automotive and aircraft engines show that the wave shapes encountered are extremely complex. Figure 1 shows oscillograms of voltages occurring in the ignition system of a typical automotive engine for the firing of one cylinder. Oscillograms of voltages on aircraft engines are similar in nature and complexity. Because of these complexities, it was thought advisable to study the performance of the voltmeters under application of a voltage of relatively simple wave form whose amplitude and shape could be controlled easily. In this way the effects of changing such variables as wave front, duration of peak voltage, and amplitude of peak could be studied. It was decided that equipment should be devised which would produce repetitive voltage surges of simple shape whose wave front, duration of peak voltage, and repetition rate would be independently variable over suitable ranges.

Figure 1. Typical oscillograms of voltages in automotive ignition system

Top and central oscillograms made at spark-coil secondary, bottom oscillogram made at spark plug

Examination of oscillograms of the type shown in Figure 1 showed that the wave fronts most frequently encountered in ignition systems would be included between the limits of 0.5 microsecond to peak voltage and about 25 microseconds to peak. Many of these waves are chopped, and many are oscillatory after reaching peak value. Hence the voltage generating equipment had to be capable of producing these variations in wave shape and wave front without too much change in the equipment. Also, the rate of repetition of voltage surges had to be adjustable over a range from the lowest likely to be encountered in a practical system to some value above which further increases in repetition rate would have no effect on the meter reading. Preliminary experimentation showed that the meters under consideration exhibited no change in reading at repetition rates above 60 per second. The lower limit considered was 7.5 surges per second. A third requirement on the voltage-generating equipment was that successive surges should duplicate each other as to amplitude, wave front, and wave shape.

Description of Apparatus

A study of the oscillograms of Figure 1 reveals that the most frequently occurring wave form is one which rises sharply to a peak and then is "chopped off" as the plug gap arcs over. Other wave forms consist of unidirectional waves which rise to a peak and then decay with

Figure 2. Simplified diagram of surge generator

Paper 47-11, recommended by the AIEE committees on air transportation and instruments and measurements for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted August 23, 1946; made available for printing November 25, 1946.

W. L. Davis was formerly with Ohio State University and is now with Battelle Memorial Institute, Columbus, Ohio; C. E. Warren is professor of electrical engineering, Ohio State University, Columbus, Ohio.

This paper is a co-operative contribution of the Air Materiel Command, Wright Field, Ohio, and The Ohio State University Research Foundation.

or without superposed sinusoidal damped oscillations. These wave forms immediately suggest that a surge generator of the type used for testing power system equipment would be a suitable device for generating surges to be applied to the voltmeters under test. Figure 2 is a simplified circuit diagram of the surge generator used in this equipment.

Capacitor C_1 is charged through R by the source of direct potential E. When the main gap is broken down by a triggering potential, C_1 discharges through R_3 and the resulting surge of potential across R_2 is impressed on the meter. The wave form of the voltage developed across R_2 can be controlled by adjusting the circuit elements L_1, R_1, R_2, and C_2. In general, the time to crest is increased by increasing R_1 and C_2. However, it is not possible to increase the time to crest indefinitely because the voltage dividing action of resistors R_1 and R_2 tends to decrease the amplitude of the surge applied to the meters. The introduction of inductor L_1 results in an oscillatory surge with a frequency of oscillation determined largely by the values of L_1 and C_1. The decrement of the oscillation depends on the values of R_1 and R_2. Independent adjustment of any one part of the wave form is in general not possible, and a surge of desired characteristics must be obtained by a trial and error process with the aid of a cathode-ray oscillograph or by calculation.[1]

The chopped wave which occurs so frequently in ignition systems was obtained with the aid of an auxiliary gap shunted across the output resistor R_2. This gap was adjusted to break down at or near the peak voltage developed across R_2, resulting in a sudden decrease in voltage similar to that which occurs when a spark plug fires. Consistent operation of this gap may be obtained by means of a "teaser" consisting of a small ball or piece of wire placed in the gap and connected to ground through a high resistance.

Figure 3. Concentric air-dielectric potential divider for observing surges

Calibration Technique

The accuracy of calibration of the crest voltmeters depends on an accurate determination of the peak output voltage of the surge generator. One possible method for calibrating the output of the surge generator depends on accurate knowledge of the oscillograph deflection sensitivity and the ratio of the capacitor voltage divider (see Figure 3). This method is not entirely reliable as it is difficult to make accurate measurements of the divider ratio because of its low input capacitance. In addition, it has been found that unless the divider is designed carefully, its ratio will be sensitive to surge magnitude and wave shape. Therefore, in view of the uncertainties involved in establishing an accurate value for the divider ratio, a more direct method of calibration was used.

The direct method of calibration is based on the fact that the discharge of a pure capacitance into a pure resistance will produce across the resistance a surge voltage of peak value equal to the maximum steady voltage across the capacitor prior to discharge. If the surge generator circuit elements L_1, R_1, and C_2 of Figure 2 are reduced to zero or to minimum values inherent in C_1, R_2, and auxiliary apparatus, the peak surge voltage developed across R_2 will be within 95 to 99 per cent of the maximum voltage to which C_1 is charged prior to the breakdown of the main gap. The maximum voltage across C_1 prior to gap breakdown is measured by a calibrated resistance potential divider and an electrostatic voltmeter. This technique results in an over-all calibration of the capacitor divider and oscillograph. It has the additional advantage that after a calibration has been established for any set of surge generator constants, the electrostatic voltmeter readings are directly related to peak surge output, and the electrostatic voltmeter readings may be used directly for additional calibration runs.

As indicated previously, the performance of the potential divider coupling the oscillograph to the surge generator output is of considerable importance and must be given careful attention if reliable calibrations are to be achieved. Without going into the details of the design and application of the several types of dividers[2] it can be stated that the capacitor divider is suitable for the range of voltages and surge wave forms encountered in this problem.

Experimentation with several designs of capacitor dividers employing solid low-loss dielectrics and relatively small electrode areas showed that their ratios were sensitive to surge wave shape and magnitude. An analysis of these designs led to the conclusions that their erratic behavior was caused by corona formation at the electrode edges and in the air spaces between the solid dielectric and the electrode surfaces. Therefore, a concentric type divider was constructed in which every effort was made to eliminate series combinations of air and solid dielectric and to provide large smooth areas of electrode surface with air as the principal dielectric. The salient features of this divider are shown in Figure 3.

The divider consists of three concentric cylindrical electrodes. The center high-potential electrode is supported by a large rod of polystyrene. The intermediate electrode is centered with respect to the outer by six small cylindrical pieces of the same material. The cathode-ray deflection plates are connected to the divider output (intermediate and outer electrodes) by a shielded concentric cable whose capacitance forms part of the low side of the divider. Provision is made for connection of mica capacitors between the outer two electrodes in order

Figure 4. Block diagram illustrating method of synchronizing oscilloscope and surge generator output

to adjust the divider ratio. When this divider first was put into operation, erratic results similar to those obtained with previous dividers were observed. However, when the concentric cable connecting the divider to the oscillograph deflection plates was changed from a cable with beaded insulation to one with flexible solid insulation, all evidences of erratic behavior disappeared.

Auxiliary Circuits

As a cathode-ray oscilloscope was used to observe wave shapes and to provide means of voltage calibration, it was necessary to devise auxiliary circuits for synchronizing the oscilloscope with the surge generator output. The total sweep time on some of the shortest duration transients was of the order of three microseconds, so that a rather precise synchronizing method was necessary in order to realize a reasonable percentage of synchronizations. Two synchronizing methods were developed, both of which will be explained by reference to Figure 4.

In the block diagram of Figure 4, the sequence of operation begins with the synchronous pulse generator, whose output is a sequence of positive steep wavefront voltage pulses equally spaced in time. In the first method of synchronizing the switch S is closed, so that the pulses are fed to the ignition coil interrupter and to the cathode-ray oscilloscope delay circuit. Two trains of events are thus initiated, one leading to the breakdown of the main surge generator gap G, the other in starting the oscilloscope beam and sweep circuits. The ignition coil interrupter, which is tripped by the synchronous pulse generator, puts out voltage of rather steep wave front and several thousand volts amplitude. Gap G_1 then breaks down, and gap G_2 is triggered by the steep voltage surge appearing on its teaser. Capacitor C_3 then discharges rapidly through the primary of the aircore transformer, inducing a high voltage of steep wave front in the secondary winding. The sudden voltage surge at the teaser of gap G trips the surge generator. All gaps were adjusted to break down long before their respective tripping voltages reached maximum open-circuit values. In addition all tripping voltages had very steep wave fronts, thereby assuring reliable and consistent gap breakdowns. In the foregoing train of events the principal time delay between the pulse from the synchronous pulse generator and the tripping of gap G occurs during the rise in voltage of the ignition coil interrupter output circuit. In the meantime the same pulse which tripped the ignition coil interrupter has also tripped an electronic delay circuit in the oscilloscope. The output of this delay circuit is a pulse which turns on the oscilloscope beam and sweep circuits. The time delay introduced in the oscilloscope is continuously adjustable over a range of the same order of magnitude as the fixed delay introduced by the voltage rise of the ignition coil interrupter. Thus the time interval between tripping of the oscilloscope beam, and sweep and discharge of the surge generator is controlled by adjustment of the oscilloscope delay circuit.

The second method of synchronizing is illustrated by Figure 4 with switch S open. Here the only change is the addition of an auxiliary electronic delay circuit between the synchronous pulse generator and the ignition coil interrupter. The additional delay circuit adds some flexibility to the system because adjustable delays are then available in both channels. Such an arrangement would have great value where no appreciable delay is inherent in the system. In attempting to synchronize with systems of

Figure 6. Oscillograms of surge generator output voltages

a—0.5-microsecond front, 1-megacycle timing wave
b—2.0-microsecond front, 1-megacycle timing wave
c—4.0-microsecond front, chopped, 0.2-megacycle timing wave
d—23-microsecond front, chopped, 0.2-megacycle timing wave

small inherent delay it is difficult to adjust the oscilloscope delay circuit for very short delays and still attain consistent synchronization. Hence the additional delay circuit in the system tripping channel permits the use in both channels of longer delays which are more easily produced and controlled.

Details of Auxiliary Circuits

In the following text reference will be made to Figure 5. The high-voltage supply for the surge generator is a voltage-doubling circuit using two type-*GL 8020* high vacuum diodes. Two 25,000-volt 0.02-microfarad capacitors in series constitute the output circuit of the doubler and also serve as the main capacitor of the surge generator. The surge generator is shown in the upper right hand corner of Figure 5 and has been discussed already.

The synchronous pulse generator is shown in the lower left corner of Figure 5. Its power supply is a simple full-wave rectified *R-C* filtered type. The plate supply for the *6N7* is regulated by a *VR-150* regulator tube. In operation the 0.005-microfarad capacitor, connected between ground and the plate of the *2050*, is connected through 6 megohms to the plate supply voltage. If a positive pulse is applied to the *2050* grids, which are biased about 5 volts negative to the cathode, the *2050* suddenly will discharge the 0.005-microfarad capacitor to ground through the 25,000-ohm resistor. In this way a pulse of steep and well-defined wave front is obtained across the 25,000-ohm resistor. The presence of the 6-megohms in the *2050* plate circuit allows the grids to regain control of the tube before the plate voltage can rise again to ignition potential. Positive pulses for tripping the *2050* are obtained from the *6N7*, which is connected as a flip-flop type trigger circuit. The *6N7* cathode-biasing 25,000-ohm potentiometer is adjusted to permit the circuit to flip-flop without external signal on either grid or cathode. The oscillation frequency can be varied by means of the 6-position selector switch. Frequency stability is obtained by adding a small 60-cycle synchronizing voltage to the right-hand grid of the *6N7*. The synchronizing voltage is obtained by capacitance coupling to a 6.3-volt filament winding on the power transformer. Thus, the pulse generator will put out pulses synchronous with the power supply frequency at rates from 60 per second to 7.5 per second.

The ignition coil interrupter is shown in the lower right corner of Figure 5. In this circuit the 2-microfarad capacitor is charged to a direct voltage whose magnitude is controlled by a variable autotransformer. The type *FG-17* thyratron is arranged to discharge the capacitor through the primary coil of an ordinary automobile ignition coil, thus inducing a high voltage in the coil secondary. The *FG-17* is tripped by positive voltage pulses supplied to its grid from the synchronous pulse generator. The induction coil output is used to trip the surge generator as previously described.

Figure 8A (left). Calibration data for sphere-gap voltmeter

Figure 8B (right). Calibration area for sphere-gap voltmeter

A—Area of most probable wave fronts

cuit is not shown, but it consists of a 1-shot multivibrator[3] utilizing pentodes to produce a square negative pulse whose width or duration is continuously variable over the desired delay range. This pulse is differentiated by a simple capacitance-resistance circuit, so that the output of the delay circuit consists of a negative pulse followed by a positive pulse. The interval between pulses constitutes the required delay.

Results

Figure 6 shows oscillograms of several voltage surges used in crest-voltmeter calibrations. Figure 6*a* shows a 0.5 microsecond wave front with a slowly decaying exponential tail. It is one surge picked at random from a sequence of surges repeating at the rate of 15 per second. Figure 6*b* shows three traces of a 2-microsecond wave with an oscillatory tail. These three waves were also picked at random from a sequence of surges and are shown here to illustrate the accuracy with which the surge generator repeated itself. Figure 6*c* shows a chopped wave with a 4-microsecond front, and 6*d* shows chopped waves with 23-microsecond fronts.

Oscillographic records of the type shown in Figure 6 were used to calibrate several types of crest voltmeters. The results for two of the meters are included here. The Hooven voltmeter (see appendix), whose calibration data are given in Figure 7, is an electronic type meter. Figure 8 shows calibration data for a sphere-gap type meter. In Figures 7*A* and 8*A* are plotted the experimental data for the various wave fronts from 0.5 microsecond to 23 microseconds. The symbols used for each wave front are tabulated in a legend on each figure. For the Hooven meter, whose scale was divided into 100 parts, a dotted straight line was drawn to represent the mean of the data plotted. For the sphere-gap meter the dotted line represents the ideal calibration curve.

For most of the meters investigated, the data for the various wave fronts were quite scattered, so that no single curve could be drawn as a calibration curve for a range of wave fronts or even for a single wave front. Curves for single wave fronts would be of little value anyway unless the wave form of the voltage being measured was known. It was thought that greater utility would result from the pair of lines enclosing the calibration points for the wave fronts most likely to be encountered in ignition voltage measurements. Thus, Figure 7*B* for the Hooven meter has a pair of lines with the area between the lines crosshatched. This area encloses the calibration points obtained for all wave fronts from 2.0 microseconds to 23 microseconds, inclusive, except some of the 2-, 4-, and 23-microsecond chopped waves above 18 kv. The area between the curved line and the upper line of the crosshatched area encloses the points obtained with the 2-, 4-, and 23-microsecond chopped waves. Hence a meter reading of 40 on a wave whose front lies between 2.0 and 23 microseconds would indicate a true peak voltage between about 10 and 12 kv. The calibration area of Figure 8*B* for the sphere-gap type meter is so broad that this meter is virtually useless for general use on systems where the wave front is unknown.

With the type of calibration area described here a meter reading on a typical ignition system can be interpreted to mean that the true peak voltage lies between the upper and lower limits, specified by the crosshatched area of the calibration sheet. The value of any meter for general use on ignition systems can be judged by the interval between the upper and lower limits, or by the width of the crosshatched calibration area. The most suitable meter will have the most narrow calibration area.

In addition to error caused by sensitivity to wave form, a second and perhaps more important consideration is that in most cases met in a practical ignition system the peak voltage being measured is determined by the breakdown potential of a gap, such as a spark plug or distributor gap. It is well known that such breakdown potentials vary considerably on successive breakdowns, and the best that any of the meters investigated can do is to give an average indication depending on the internal circuit and mechanism.

Figure 9. Circuit diagram of Hooven voltmeter

Figure 10. Cross section of part of Hooven voltmeter showing concentric shielded construction

Of the two possible sources of error, the preceding investigation has shown the dependence on wave form. The error resulting from the averaging mechanisms of the meters was not studied.

Conclusions

Circuits and techniques have been described which have proved satisfactory for the production of consistent and accurate potential wave forms adjustable over a considerable range of peak voltage, time to crest, wave shape, and repetition rate. Application of these circuits to the calibration of ignition crest voltmeters has resulted in a better understanding of the various factors influencing meter performance and has indicated the useful range of application of each of the several meters tested.

Several other applications of the apparatus are suggested in the following list:

1. A study of the design and performance characteristics of spark gaps used in various control circuits or as voltage measuring devices.

2. A study of the characteristics of insulation subject to repetitive transient voltages.

3. As a source of transient voltage or current wave forms for use in electrical analogy or electric model computors.

Appendix

Figure 9 shows a circuit diagram of the Hooven voltmeter, developed by F. J. Hooven, Dayton, Ohio and Figure 10 shows a drawing which is a combination cross section and circuit diagram of part of the meter.

The triode T and the diode D are both type *955* miniature triodes. The triode T has a positive voltage applied to its grid. When the plate of T is made negative to the cathode, the potential distribution within the tube will control the grid current, the more negative the plate the smaller the grid current. The microammeter is arranged to read the drop caused by the grid current in the 0.25-megohm resistor, thus providing a measure of the negative voltage at the plate of T.

The unknown voltage is applied at the point marked "input" in Figure 9. The capacitance C_1, which is of the order of two or three micro-microfarads, is the capacitance between the brass rod and brass cup at the top of Figure 10. The upper brass skirt of Figure 10 has capacitance C_3 to the long steel tube containing the triodes and filament isolating transformer. The capacitance between the steel tube and the grounded lower skirt is C_3; and C_4 is the capacitance between the upper brass skirt and the enclosing brass case. The combination of C_1, C_3, C_4, and C_4 forms a capacitance voltage divider of very low input capacitance. The diode D is arranged so that with either positive or negative voltage pulses applied to the input, the point B will always be driven negative to ground, and the plate of T will float at an average negative voltage proportional to the absolute value of peak voltage occurring at point A. The magnitude of the voltage at A determines the microammeter reading as previously described.

Discussion

S. W. Zimmerman (Cornell University, Ithaca, N. Y.): The authors show ingenuity in adapting impulse testing technique normally used in testing high voltage power system components to a problem quite remote from the power transmission and distribution field.

This consideration of the voltages in ignition systems shows that many of the behavior effects studied as system problems in the power field are repeated in miniature in ignition systems, as, for example, the change in wave shapes measured in different parts of the system apparent from the records in Figure 1 of the author's paper.

While sphere gaps appear to be unsuitable for means of making measurements in this study because of the wide range of rates of voltage change encountered in this problem, it should not be inferred that they have lost their usefulness as a means of measurement. Clean irradiated sphere gaps in the 10-kv range, for example, generally will have a range of values of impulse spark potential that is more nearly five per cent of the average value for a given wave front than any range that might be implied by reference to the data presented in Figure 8*B*.

The length and character of the connections to the sphere gap will have an effect on the apparent voltage especially where steep wave fronts are involved. The construction of the voltmeter in Figure 10 establishes a means of keeping this lead constant between measurements.

A consideration of the undamped or damped 23-microsecond case of Figure 8*A* appears to indicate a slight discrepancy in the zero setting of the gaps as well as a slight shift in the scale factor of the instrument. The steeper front waves of course will appear to have a higher true voltage because of the characteristic "turn up" of the volt–time curve of the sphere gaps in the shorter time regions. Clean irradiated gaps are expected to be more consistent than some of the chopped wave data shown.

The Cathode-Ray Spectrograph

RUDOLF FELDT
MEMBER AIEE

CARL BERKLEY
NONMEMBER AIEE

IT is now 85 years since Kirchhoff and Bunsen introduced the spectrograph as a tool for analytical research. Despite this long existence, it is only during the last two decades that the spectrograph has developed from a pure research instrument into a tool of more widespread use.

Many types of recording spectrographs are commercially available, and their technical development has paralleled the increasing need for finer and faster instruments. These instruments range from the slow, extremely accurate types requiring tedious photographic procedures to the direct recording photoelectric instruments, as exemplified by the Hardy spectrograph. This spectrograph, which is at present the fastest commercially available instrument, produces a complete spectrum in the order of minutes. Instruments of this kind are rather expensive and require highly trained personnel. This limits their use to a relatively small number of well-equipped laboratories. In addition to this limitation, even the best presently available spectrographic instruments are deficient when the following problems are encountered:

1. Investigation or control of rapidly changing spectra. Examples—rapid chemical reactions, half-lives of compounds, fluorescence, and light sources of varying intensity and color.

2. Problems which require telemetering or simultaneous transmission of spectrographic data to several points. Examples—chemical process control, pyrometry, and transmission from inaccessible locations.

3. Production control.

(a). Where continuous monitoring is desired as in the cases of dye and textile industries.

(b). Where the analysis of a large number of samples is necessary.

(c). Where the use of unskilled personnel is desirable.

Wherever it is found necessary to make such measurements more rapidly and economically, electronic methods will prove a desirable solution.

The use of cathode-ray oscillograph techniques has come into widespread prominence whenever such rapidly acquired information is to be recorded or made visible. Several attempts have been made to produce instantaneous spectrograms on cathode-ray tubes, notably a mechanical scanner using a vibrating prism, by D. Ulrey,[1] and a rotating slit by H. A. Snow (see reference 2). Both of the two mentioned instruments have serious mechanical limitations, inherent in this type of construction. In the instrument to be described the mechanical difficulties have been overcome, and the electrical problems greatly simplified by the use of a mechanically resonant synchronous scanning system.

Problem for Which Developed

This instrument originally was developed to study the color and duration of the light emitted from cathode-ray tube phosphors when excited with electric pulses whose duration was of the order of microseconds. Such problems exist in connection with the observation of radar patterns, the viewing and recording of single and repetitive transients, and in television. With certain modifications this instrument is expected to find, in addition to the usual spectrographic problems, widespread application in problems heretofore difficult to interpret with the usual spectrograph.

General Description of Cathode-Ray Spectrograph

The instrument produces a complete spectrogram within a small fraction of a second. In the present design this value

Figure 1. Schematic diagram of analyzer optical system

Paper 47-13, recommended by the AIEE committee on instruments and measurements for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted October 3, 1946; made available for printing December 27, 1946.

RUDOLF FELDT and CARL BERKLEY are both with Allen B. DuMont Laboratories, Inc., Passaic, N. J.

Figure 2(left). Developmental model of the cathode-ray spectrograph

Figure 3. Scanning mirror and vibrator resting on absorption cell

is 1/240 second, but could be either shortened or lengthened if necessary. The record is produced in the form of a luminous pattern on the face of a cathode-ray tube which is used as indicator. Figures 7 through 10 are typical. In general, the instrument is composed of two parts—the analyzer and the indicator unit. The analyzer contains conventional means for dispersion, that is, condensing system, prism, entrance and exit slits. The rapid operation of the analyzer is obtained by the use of a vibrating mirror which scans the image of the spectrum with the aid of an exit slit placed in front of a photocell. This scanning rate is, for convenience, a multiple or submultiple of the power line frequency, and the mirror motion is sinusoidal. The output of the photocell is, consequently, directly proportional to the intensity of any individual part of the spectrum at any given instant in the scanning cycle. This output, after amplification, is applied to the indicator unit which consists of a conventional cathode-ray oscillograph. A deflection proportional to light intensity therefore is obtained in a vertical direction on the cathode-ray tube. A sweep synchronized with the mirror motion is applied to the horizontal deflecting plates. As a result a conventional spectrogram is obtained in which ordinates represent relative intensity and abscissae wave lengths. Because of the high scanning rate the spectrogram obtained on the cathode-ray tube appears as a continuous pattern without flicker. Changes in the spectral characteristic of the light source appear to be recorded instantaneously. The comparison of changes is facilitated by the use of long persistent screens on the cathode-ray tube. Continuous and permanent records may be obtained by conventional photographic procedures.

Figure 1 shows the schematic layout of the essential elements of the cathode-ray spectrograph. A developmental model of the instrument is shown in Figure 2. The indicator, which in this case is a standard DuMont cathode-ray oscillograph modified for the purpose, is connected to the analyzer by a multiconductor cable which can be made of any desired length. The analyzer in turn consists of three interconnected separable units.

Figure 4. Analyzer unit disassembled. From left to right—light source, condensing system, scanning unit

1. The source.
2. The condensing system.
3. The dispersing and scanning means

The source is usually a concentrated filament projection lamp. The condensing system is conventional consisting of two plano-convex condensing lenses and a cylindrical lens calculated to make all the light enter the entrance slit. A 3-element prism is used for dispersion. The scanning means is a vibrating mirror shown in Figure 3, which moves the image of the spectrum back and forth over the exit slit.

The whole device acts essentially as a monochromator in which the wave length measured depends upon the angle of the vibrating mirror. The mirror consists of a mechanical resonant system which is tuned to a multiple of the line frequency and is energized through a magnetic coil from the power line.

The angular motion of the mirror is adjustable by means of a series rheostat and easily covers the dispersion of the prism throughout the visible range. The photocell used may be any one of the series of 9-stage photomultipliers recently made available. A type *1P22* generally has been used, which, in conjunction with a Wratten number *101* filter, gives an over-all response approximating the visibility function. In order to be able to use the instrument at a location remote from the photocell, which necessarily must be in the proximity of the test object, a cathode follower impedance matching stage is used to feed the signal through the cable into the oscillograph. The oscillograph may be either a-c or d-c coupled. It is preferable to use d-c coupling in order to obtain a fixed reference level. Provision is made for inserting transmission samples or standard absorption cells into the optical path through the top of the analyzer unit. Controls on the analyzer provide for mirror amplitude, entrance slit width, and sensitivity. The slit and sensitivity are adjusted to give maximum resolution, depending on the intensity of the source.

The three units (light source, condensing system, and scanner) may be easily assembled or disassembled at will without tools. Figure 4 shows the three elements of the analyzer unit disassembled, which is done by turning the knurled screws. The ease of separation and replacement of the various units is of considerable

advantage with regard to flexibility of operation. For example, the light source may be removed easily, leaving the condensing system attached. Any other light source for testing or calibration purposes, then may be plugged into the opening of the first light gathering lens in the condensing system. Similarly, the condensing system may be removed and any other optical system whose light transmission characteristics are desired may be used to replace it.

Figure 5. Spectrogram of a cadmium mercury arc used as a calibrating light source

Detailed Description

Some of the particular design features of the previously described parts may be of interest.

Light Source

This instrument was designed to accept light from a cathode-ray tube spot no greater than one centimeter in diameter. Therefore, it is suitable without modification for all other light sources of similar size as arcs, spark gaps, and incandescent filaments. For transmission measurements a concentrated filament projection lamp is used as a source. The color temperature of the lamp may be set by measuring voltage and current. This source may be removed, and a concentrated low pressure cadmium mercury arc may be inserted for wave length calibration. Figure 5 shows the spectral lines of this source.

Scanning Unit

Because the mirror is tuned to mechanical resonance for the frequency desired, it requires only very little energy to produce the necessary amplitude, most of this energy being expended in overcoming air resistance. The actual current through the driving coil is of the order of one milliampere at 110 volts. The corresponding angular deviation of the mirror is 15 degrees. The entire mirror assembly may be rotated about an axis in order to scan about any desired portion of the spectrum. When this is done the wave length scale becomes greatly expanded.

Mechanical Considerations

It is necessary to isolate very carefully the motion of the mirror from the rest of the unit in order to avoid mechanical vibration effects in other parts of the instrument. This isolation is accomplished first by attaching the mirror to a mass which acts as an inductance for this frequency. The rubber grommets then serve to absorb any residual motion at the scanning frequency.

The design of the resonant reed itself presents some interesting problems. The linear sweep, which generally is used with this instrument, is synchronized from the line frequency. The reed is vibrated by the same power source. In order to obtain the largest amplitude possible with the least power dissipated in the magnetic coil, it is necessary that the mechanical Q be very high. However, this makes a limitation on the resolving power that can be obtained on the final instrument. If the Q is made very high, any line frequency change will cause a large change in the phase of the mirror motion with respect to the line. This will be represented on the oscillograph by an apparent change of wave length, as the synchronization of the sweep occurs at almost the same phase of the sine wave over considerable variation in frequency. In the case of line voltage variations, the mirror amplitude will change resulting in a change of the wave length scale. For these reasons it is necessary to control the line voltage very carefully. The Q of the circuit must be made low enough so that phase variations are not serious. Obviously, for power sources having different frequencies, it must be possible to either tune the mirror unit or to replace it by other units of different frequencies. In locations where the line frequency is not sufficiently dependable these difficulties can be eliminated entirely by the use of wave length markers applied as blanking pulses to the grid of the cathode-ray tube. These marker signals may be obtained by optical means.[3]

Photocell

With the present unit, the spectral response ranges available are somewhat limited. It is desirable for many cases to obtain not only the visual response referred to by the use of a suitable filter and photocell combination, but also a flat response characteristic. This can be obtained by changing the optical design in such a way that masks are placed in a stationary focal plane of the spectrum to accomplish this result, or to obtain any arbitrary spectral sensitivity. The masks are superimposed on the real spectrum image so as to reduce the over-all transmission for those wave lengths where it is desired to flatten the peaks caused by the photocell and light source characteristics. Various other methods have been proposed for rapid scanning of the spectrum and indication of the results on a cathode-ray tube. One of these[4] uses a moving prism. The size of the prism required obviously precludes the use of high scanning rates. Another method which has been used by Snow (see reference 2) is one in which a rotating mirror is used. The major disadvantage of this scheme lies in the fact that the spectrum is being scanned by the photocell during only a small portion of the cycle, and this requires the use of wide band amplifiers. Similarly, a mechanical rotating system

requires much more attention than an almost frictionless one as used in this instrument, particularly at these high speeds. Another completely electronic spectrographic analyzer using an iconoscope has been patented by H. A. Snow.[5] Unless the spectroscopist is interested in a fidelity of color analysis similar to the fidelity of television images, this method will be of little value.

Performance

Scale Linearity

The scale linearity is a complex function depending on the dispersion of the prism and the sinusoidal motion of the mirror. The net results can been seen in Figure 6. This can be corrected to give almost any desired result by the introduction of arbitrary nonlinearities into the sweep. The scale in the figure permits the measurement of transmittance directly without the necessity of having to compensate for the photocell response, as indicated in the foregoing text.

Wave Length Coverage

The present mirror covers the visible range. Also, it can be rotated and its amplitude reduced to scan a small portion with increased electrical resolution if necessary. Photocells and optics can be used with this system to extend the sensitivity into the ultraviolet, and, to some extent, into the infrared.

Resolution

In the cathode-ray spectrograph, as in other optical instruments, the ultimate resolution is limited by the quality of the optical parts. In the present developmental model the resolution is 35 millimicrons. A second model is expected to have a resolution better than 5 millimicrons.

Sensitivity

It is difficult to state the performance of this device in terms of arbitrary light sensitivities. However, it has been possible to measure the amplitude throughout the visible spectrum of the light from cathode-ray tube phosphors excited by electric pulses as short as one microsecond.[5] This is done by a procedure described in the appendix.

Applications

The cathode-ray spectrograph is not intended to compete with existing spectrographs but rather to make possible spectrographic measurement of sources or samples subject to variations too rapid to be recorded completely by direct photographic methods. In general, this device will find its greatest use in the measurement of similar transient phenomena such as the forementioned spectral distribution of cathode-ray tube pulses, the color of intermittently lit lamps, the color of arcs such as are used in spectroscopy, and the color of flames. Some typical examples follow.

Nonintermittent Light Sources of Varying Intensity. The upper curve in Figure 7 shows the characteristic of an a-c operated tungsten light source operated at 3,200 degrees Kelvin as seen by the spectrograph. The photocell is a type *1P22* whose peak sensitivity approximates that of the human eye. This curve represents the over-all characteristic of the spectrograph when used for transmission measurements, because this is the lamp used in the instrument. The letters *B* and *R* represent the blue and red ends of the spectrum.

Transmission Measurements. Transmission measurements, as percentages, may be made directly by using the scale of Figure 6. The lower curve in Figure 7 shows the transmission of a chemical solution. Figure 8 shows the characteristic of a didymium filter compared with the total characteristic. The peaks and valleys of this spectrum can be used for a rough wave length calibration. These two cases are typical of applications in the chemical and textile industry. The varying color of a dye bath or the strength of a photographic filter may be checked constantly in production by this method.

Slowly Changing Light Sources. Figure 9 shows four spectrograms obtained from a mercury arc light source at different times after starting. It can be seen how the light output increases markedly as the lamp warms up and the mercury vaporizes.

Despite the fact that this light source is intermittent at a rate of 120 cycles per second, a stable picture is obtained because of the synchronization of the mirror frequency with the line. As most light sources are a-c operated, this instrument is a convenient tool for their color study.

Figure 10 shows the spectrogram of the color of the Sylvania recording lamp. The two traces were recorded at low and high currents.

Intermittent Light Sources. Figure 11 shows a type *5FP11* cathode-ray tube pulsed with 100 microsecond flat top pulses at a repetition rate of five kc. Each pulse causes the light output to reach a peak value rapidly corresponding to this portion of the spectrum. This light then decays until the next pulse occurs. Because the pulse length is short with respect to the scanning cycle and the decay is rapid, the individual decay curves are very nearly the decay characteristics for each particular part of the spectrum. If the repetition rate of the pulses is not synchronized with respect to the mirror motion, an envelope of the peaks is obtained, as in Figure 12, which represents the maximum fluorescent light output of the phosphor. This measurement is of importance in the case of the screen materials to be used for continuous film recording.

Figure 13. *P7* screen under conditions similar to those in Figure 11 with repetition rates 5 and 10 kc

It also can be seen in Figure 12 that in the center of the spectrum the light energy has no time to decay to zero before the arrival of a new pulse. A second envelope therefore is formed on the bottom which represents the phosphorescence after 1/120 second according to the scanning rate. The amplitude of this second envelope is very small in this case, because the *P11* is a short persistent screen material. This effect is illustrated much better in Figure 13 which shows the characteristic of the long persistent *P7* screen at different repetition rates. The illustrations show clearly the lower efficiency and changed phosphorescent color with increasing repetition rate.

In connection with the usual arc spectroscopy, this method will offer a particular advantage; for example, when a number of compounds are being volatilized in the arc, the presence of interfering compounds may mask a small trace of an impurity. Where this impurity exists in discrete particles, it is possible to take motion pictures during volatilization and to study only the frames which show the characteristics of the desired component.

In connection with the studies of the optimum combustion conditions for jet engines, it is expected that this device will prove useful, particularly when it is desired to use the instrument in the small amount of space available in airborne missiles.

Process Control

This instrument should have wide application in the many chemical and industrial process controls where a continuous indication is required of the state of the product being tested. For example, a reaction may be carried to the correct point, as shown by the spectrogram, and then automatically stopped. This can be done whenever the pattern on the screen reaches a predetermined shape. The indicator, in these cases, may be located in the control room of the plant, while the analyzer is in a remote location.

Transmission From Remote Locations

The possibility of transmitting spectral information in a short time should prove of considerable advantage. This information, of course, can be sent over wires as in the case of the plant, or may be modulated upon a carrier and demodulated at another location, as is desirable in the case of aircraft.

Colorimetry

Analysis. Because this instrument can analyze colors which constantly are changing, it is expected to prove superior in measurements such as the color of television screens. Such colorimetry is,

at present, quite difficult, because of the presence of flicker and the continuous change of color, caused by phosphorescent decay.

International Commission on Illumination Co-ordinates. Because the spectrograms already have been converted to electrical form by this instrument, it becomes very easy to integrate these electrical values by known circuit methods in order to obtain integrated or proportional values, such as are used in the International Commission on Illumination Co-ordinates.

EDUCATIONAL

Finally, this instrument obviously will prove to be a useful tool in the educational and industrial fields where actual graphical demonstrations of color phenomena can be produced and shown to large groups of people with the aid of a projection oscillograph. It has been found that the education of color matchers and similar personnel in the rudiments of color analysis is of considerable help in the manufacture of a more uniform product.[6]

Although the foregoing discussion has been concerned mainly with transmission measurements, it is possible to use the instrument also for reflective measurements as well.

Appendix

In a particular case the energy delivered to screen was

$$10^4 V \times 5 \times 10^{-4} A = 5 \text{ watts}$$

$$= 5 \text{ volt } \frac{\text{coulombs}}{\text{second}}$$

if 1/10,000 of total energy enters the slit for a band centering about 5,500 angstroms and the average energy per photon in this band[6]

$$E = \frac{12.4 \times 10^3}{5.5 \times 10^3}$$

$$= 2.25 \frac{\text{electron volts}}{\text{photon}}$$

The entering power was then

$$\frac{5 \times 10^{-4} \dfrac{\text{volt coulombs}}{\text{second}}}{1.60 \times 10^{-19} \dfrac{\text{coulombs}}{\text{electron}}} \Bigg/ \frac{\dfrac{\text{electron volts}}{\text{second}}}{\dfrac{\text{electron volts}}{\text{photon}}}$$

$$= 1.39 \times 10^{15} \frac{\text{photons}}{\text{second}}$$

For a 10^{-6} second pulse this is 1.39×10^9 photons.

Dimensionless Analysis of Servomechanisms by Electrical Analogy—I

G. D. McCANN
MEMBER AIEE

S. W. HERWALD
ASSOCIATE AIEE

IN a previous paper[1] general solutions were presented in dimensionless form, giving the transient response characteristics of the basic variable-voltage angular-position servomechanisms with simple error control alone and with error control plus optimum anticipation time. This paper continues the analysis for error control servomechanisms having the three most important forms of *RC*-feedback damping; that is, feedback from generator field current, feedback from generator armature terminals, and feedback proportional to the velocity of the regulated system. All solutions were obtained with the mechanical transients analyzer. The actual physical systems together with the equations defining their performance are presented together with the electrical analogies set up on the analyzer. The general solutions are given in dimensionless curve form for the practical range of time constants and damping ratios.

The Servomechanisms and Their Analogies

The dimensionless form used for representing the solutions of such servomechanisms has been treated in detail in references 1, 2, and 3. The basic parameters will merely be tabulated here. Referring to Figures 1, 2, 3, and 4

θ_i = angular position of reference system to be followed

θ_o = angular position of regulated system

$\theta = \theta_i - \theta_o$ = error angle

t_a = armature time constant

t_f = field time constant

K = stiffness constant

I = total system inertia

c = actual mechanical damping of armature circuit

$r = \dfrac{c}{2\sqrt{KI}}$ = ratio of actual to critical damping

$\omega_n = \sqrt{\dfrac{K}{I}}$ = undamped natural frequency of simple error-control system with no time delays

The latter two constants are the basic dimensionless parameters defining the simple error-control system.[3] All time constants are put in dimensionless form[1-3] through multiplication by ω_n.

Also, the actual solutions are obtained for a suddenly applied velocity ω_1 of the system to be followed. Referring to the illustrative solutions for the error angle given on the curves of Figures 5 to 9, the solutions are defined in terms of the crest overshoot θ_{max} and the time t_1. In the curves giving the general solutions, θ_{max} is put in dimensionless form by dividing by θ_{ss} (the steady-state error angle for suddenly applied constant velocity).

$$\theta_{ss} = \frac{2r\omega_1}{\omega_n}$$

The time t_1 is made dimensionless through multiplication by ω_n.

RC-Feedback From Generator Field Current

Figure 2*a* shows a schematic diagram of the actual system. The complete performance equation as shown is derived in the appendix. Only two parameters (in addition to those for the simple error control system) are required to define the system completely. These are the dimensionless constant A_2, which is the voltage gain around the feed-back loop, and the *RC*-feedback time constant t_d which is put in dimensionless form through multiplication by ω_n. The electrical analogy set up on the transients analyzer for obtaining the solutions is shown in Figure 2*b*. Analogy *A* of Figure 1 was used to represent the motor-generator electrical-

$$M_c = \frac{K(\theta_i-\theta_o)}{(1+t_f p)} - \frac{A_2 t_d p M_1}{(1+t_f p)(1+t_d p)}$$

$$E_c = \frac{A_0}{C_0}\frac{(\theta_i-\theta_o)}{(1+t_f p)} - \frac{A_0\frac{r_d}{R_d}t_d p\, E_1}{(1+t_f p)(1+t_d p)}$$

$$\frac{K(\theta_i-\theta_o)}{(1+t_f p)} - \frac{A_2 t_d p\left[(1+t_d p)\,\frac{I}{2}p^2\theta_o + c p\theta_o\right]}{(1+t_f p)(1+t_d p)} = (1+t_d p)\, I p^2\theta_o + c p\theta_o$$

Figure 3. Basic system and analogy for variable-voltage angular-position servomechanism with *RC*-feedback from generator armature terminals

Assuming equal impedances in motor and generator armatures

mechanical equations. Because of the internal impedance of the amplifier, the voltage at the output terminals of the last stage is not proportional to $E = M_c$. It was therefore necessary to use a parallel stage to supply the *RC*-feedback circuit as shown. If the *RC*-feedback circuit has a high impedance compared to the amplifier impedance, its voltage is proportional to the generator field current through the relation shown in the caption of Figure 1.

RC-Feedback From Generator Armature Terminals

The actual physical system and its electrical analogy are shown in Figure 3. The performance equation is derived in the appendix. The system is defined by the same parameters as used for *RC*-feedback from the generator field current. The only difference is the form of the feed-back damping. In setting up the electrical analogy, the most desirable circuit was found to be one in which the circuit representing the motor-generator armature circuit and motor torque equations was set up in dual using both analogies of Figure 1. Analogy *A* was found most convenient for applying the forcing function (constant ω_i) and for obtaining the error angle control. However, analogy *B* was required to obtain the proper voltage analogous to the generator terminal voltage in providing the *RC*-feedback.

RC-Feedback Proportional to Velocity ($p\theta_o$)

This system and its analogy is shown in Figure 4. As shown by the equation defining performance, the damping component of the control torque can be expressed in terms of the stiffness constant K, the *RC*-circuit constant t_d, and an additional time constant t_n, defined in Figure 4 and derived in the appendix. In the analogy the *RC*-feedback is easily obtained from analogy *A* (Figure 1) by inserting a resistor in the circuit through which the current ($i_1 \equiv p\theta_o$) flows.

Dimensionless Data in Curve Form

The general solutions in dimensionless form giving the optimum damping parameters and the system response are presented in the curves of Figures 5, 6, 7, and 8 for the respective damping ratios of $r =$ 0.2, 0.4, 0.6, 0.8, and 1.0. Each figure

Figure 4. Basic system and analogy for variable-voltage angular-position servomechanism with *RC*-feedback proportional to velocity $p\theta_o$

Kt_n defined as equal to $A\frac{r_d}{R_d}g_t$

t_n is a time constant (see appendix)

$$M_c = \frac{K(\theta_i-\theta_o)}{(1+t_f p)} - \frac{A\frac{r_d}{R_d}t_d g_t p^2\theta_o}{(1+t_f p)(1+t_d p)}$$

$$E_c = \frac{A_0(\theta_i-\theta_o)}{C(1+t_f p)} - \frac{A_0\frac{r_d}{R_d}R_f r_f p^2\theta_o}{(1+t_f p)(1+t_d p)}$$

$$\frac{K(\theta_i-\theta_o)}{(1+t_f p)} - \frac{K t_n t_d p^2\theta_o}{(1+t_f p)(1+t_d p)} = (1+t_d p)\, I p^2\theta_o + c p\theta_o$$

Figure 5. Dimensionless performance curves and optimum damping parameters for $r = 0.2$

A—*RC*-feedback from generator field current
B—*RC*-feedback from generator armature terminals
C—*RC*-feedback proportional to velocity

gives solutions for the three types of feedback. There are four sets of curves for each type of feedback and value of damping ratio. Two give the system performance in terms of the ratio of crest overshoot to the steady-state error angle θ_{max}/θ_{ss} (for a suddenly applied constant velocity) and the dimensionless duration of the initial overshoot $\omega_n t_1$. The other to give the optimum values of the time constant of the *RC*-feedback circuit $\omega_n t_d$ and the gain around the feedback loop A_3 for feedback from generator field current and armature terminals or the time constant $\omega_n t_v$ for feedback proportional to velocity.

For the range of parameters covered, damping greater than 85 per cent always could be obtained giving solutions as illustrated. For this reason the per cent damping was not plotted.

Polarity of RC-Feedback

It was found that for a narrow band of parameters, positive feedback gives positive damping with *RC*-feedback from generator field current and from the generator armature terminals. This band is for r less than 0.4 and low values of $\omega_n t_d$ and $\omega_n t_f$ (below about 0.5). A comparison of solutions obtained in this range with both polarities of feedback is given in Figure 10. Positive feedback gives a better solution with much less crest overshoot and more rapid decay to the steady-state value. However, the required amount of feedback is very critical and (as shown by the oscillograms) slightly too much feedback will cause the system to break into relatively high frequency undamped oscillation. For this reason positive feedback will probably seldom provide a practical solution.

Analysis of Data

The principal variations in the system performance as a function of the type of feedback and damping ratio are illustrated by the solutions of Figure 11. The ratio of θ_{max}/θ_{ss} increases with decreasing damping ratio at a rate sufficiently rapid to cause the actual value of θ_{max} to increase slightly. For instance, with case *A* of Figure 11 and $r = 1.0$, $\theta_{ss} = 1$ and $\theta_{max} = 1.9$. For $r = 0.2$, $\theta_{max} = 11.4 \times 0.2 = 2.28$. The ratio of θ_{max}/θ_{ss} at the end of the overshoot (or at t_1) also in-

Figure 6. Dimensionless performance curves and optimum damping parameters for $r = 0.4$

A—*RC*-feedback from generator field current
B—*RC*-feedback from generator armature terminals
C—*RC*-feedback proportional to velocity $p\theta_o$

creases with decreasing r, together with the value of $\omega_n t_1$.

Comparison of Types of Feedback

At the lower values of damping ratio, feedback proportional to velocity gives markedly better solutions than for either of the other two types. Referring to Figure 11, it is seen that for $r = 0.2$, this type of feedback gives appreciably lower crest overshoot with shorter times t_1 and markedly lower error at t_1. Feedback from the armature terminals provides somewhat better solutions than from generator field current at the lower values of r. For r greater than 0.8 there is no great difference between the performance with the three types of damping. Feedback from the armature terminals provides a better solution than feedback from the generator field current because of the added delay introduced by the generator armature impedance.

Typical Example

To illustrate how the data presented in Figures 5 to 9 can be used to obtain optimum *RC*-feedback values for a variable-voltage angular-position servomechanism, the following example is given. The values for the basic system parameters are the same as used for determining optimum anticipation time in the previous paper,[1] namely,

$I = 10^{-1}$ pound-inches second^2
$K = 5$ inch-pounds per radian
$R_a = 6$ ohms
$L_a = 0.10$ henry
$R_f = 100$ ohms
$L_f = 15$ henries
$b = 4$ inch-pounds per ampere
$g = 0.6$ volt per radian per second

$$\omega_n = \sqrt{\frac{K}{I}}$$
$$= 7.07 \text{ radians per second}$$

$$c = \frac{bg}{R_a}$$
$$= 0.4 \text{ inch-pound per radian per second}$$

$$r = \frac{c}{2\sqrt{KI}}$$
$$= 0.283$$

$\omega_n t_f = 1.06$
$\omega_n t_a = 0.12$

For the case of *RC*-feedback from the

Figure 7. Dimensionless performance curves and optimum damping parameters for $r = 0.6$

A—*RC*-feedback from generator field current
B—*RC*-feedback from generator armature terminals
C—*RC*-feedback proportional to velocity

generator field current, interpolating between Figure 5*A* and 6*A* for $r=0.28$

Optimum $\omega_n t_d = 9.6$
$A_2 = 5.3$
$\omega_n t_1 = 15.9$
$\theta_{max}/\theta_{ss} = 9.1$

Therefore, if in the actual servomechanism with the parameters just given the feed-back time constant t_d is made 9.6÷7.07 or 1.35 seconds, and the total gain around the feed-back loop is made 5.3 then time t_1 for the undamped half cycle that occurs with all *RC*-feedback is 15.9÷7.07 or 2.25 seconds. The maximum angular error at the motor shaft θ_{max} for a suddenly applied constant velocity ω_1 is

$$9.1 \times \frac{2r\omega_1}{\omega_n} = 0.725\omega_1$$

The damping after the first overshoot will be very high.

Using *RC*-feedback from the generator terminals for the same servomechanism system and interpolating between Figures 5*B* and 6*B* for $r=0.28$

$\omega_n t_d = 4.9$
$A_2 = 4.8$
$\omega_n t_1 = 11.7$
$\theta_{max}/\theta_{ss} = 7.0$

Then if t_d is made $4.9/7.07 = 0.69$ second and the net gain around the feed-back loop is 4.8, $t_1 = 1.65$ seconds and $\theta_{max} = 0.58\omega_1$. The damping after the first overshoot is high.

Again using the same servomechanism system but making the *RC*-feedback proportional to the output velocity $p\theta_o$ and interpolating between Figures 5*C* and 6*C* for $r=0.28$

$\omega_n t_d = 4.2$
$\omega_n T_v = 1.1$
$\omega_n t_1 = 8.4$
$\theta_{max}/\theta_{ss} = 5.9$

Then if t_d is made equal to 0.59 a second and $T_v = 0.15$ second, $t_1 = 1.2$ seconds and $\theta_{max} = 0.39\ \omega_1$. Again the damping after the first overshoot is high.

In comparing the merits of anticipation[1] and the various means of *RC*-feedback in their benefiting the performance of this particular servomechanism, they should be ranked in this order:

1. Anticipation.
2. *RC*-feedback proportional to output velocity $p\theta_o$.

Figure 8. Dimensionless performance curves and optimum damping parameters for $r = 0.8$

A—*RC*-feedback from generator field current
B—*RC*-feedback from generator armature terminals
C—*RC*-feedback proportional to velocity

3. *RC*-feedback from generator terminals.
4. *RC*-feedback from generator field current.

As anticipation requires a d-c amplifier or its equivalent and *RC*-feedback proportional to output velocity $p\theta_o$ usually requires a tachometer, the simplest method to use where the specifications to be met permit is *RC*-feedback from the generator terminals.

It should be understood clearly that the above ranking of performance merit is only for the example given and the ranking for servomechanism systems with different basic parameters may be quite different.

Appendix. Derivation of the Basic Equations for the Various Angular-Position Servomechanisms

RC-Feedback From Generator Field Current

Figure 1 gives the derivation of the two analogous electric circuits used to represent the combined electrical and mechanical equations for the motor and generator armature circuit and motor rotation. For this particular type of *RC*-feedback, analogy *A* was used as shown in Figure 2. Referring to Figure 2 the motion of the system in terms of the controller torque M_c is defined by the equation

$$M_c = (1+t_a p)Ip^2\theta_o + cp\theta_o \tag{3}$$

The controller torque M_c is composed of two components,

$$M_c = M_o + M_d$$

The first term, the error control term derived in reference 1, is

$$M_o = \frac{K(\theta_1-\theta_o)}{(1+t_f p)}$$

Referring to Figure 2 for the derivation of the second term,

$$i_d = \frac{C_d p R_1 i_f}{(1+t_d p)}$$

$$e_d = \frac{r_d C_d R_1 p i_f}{(1+t_d p)} = \frac{R_1 \frac{r_d}{R_d} t_d p i_f}{(1+t_d p)}$$

A = factor relating control torque M_c to amplifier input voltage e (torque÷volts)

A_1 = constant relating control torque M to generator field current i_f (torque÷ampere)

A_3 = gain around the feed-back loop

$$M_d = \frac{-AR_1 \frac{r_d}{R_d} t_d p i_f}{(1+t_f p)(1+t_d p)}$$

$$M_d = \frac{-\frac{AR_1}{A_1}\frac{r_d}{R_d} t_d p M_c}{(1+t_f p)(1+t_d p)} = \frac{-A_3 t_d p M_c}{(1+t_f p)(1+t_d p)}$$

R_1 has the dimension of volts per ampere and thus A_3 is a dimensionless constant. It is actually the voltage gain around the feed-back loop. Thus, as

$$M_c = M_a + M_d = (1+t_a p) I p^2 \theta_o + c p \theta_o \qquad (3)$$

the complete equation becomes

$$(1+t_a p) I p^2 \theta_o + c p \theta_o = \frac{K(\theta_1 - \theta_o)}{(1+t_f p)} - \frac{A_3 t_d p[(1+t_a p) I p^2 \theta_o + c p \theta_o]}{(1+t_f p)(1+t_d p)}$$

RC-Feedback From Generator Armature Terminals

For this type it is assumed that the motor and generator armatures have the same impedances. The terminal voltage is thus given by the equation

$$E_1 = E_g - (R_a/2 + L_a p/2) i_a$$
$$= E_g - R_a(1+t_a p) i_a/2$$

From this a mechanical torque equation can be written.

$$M_1 = \frac{b E_1}{R_a} = M_c - b(1+t_a p) i_a/2$$

Expressing i_a in terms of θ_o (from equation 1, Figure 1),

$$i_a = I p^2 \theta_o / b$$

From equation 3, Figure 1,

$$M_1 = M_c - (1+t_a p) I p^2 \theta_o / 2$$
$$= (1+t_a p) I p^2 \theta_o / 2 + c p \theta_o$$

By analysis identical for the case of *RC*-feedback from generator field current, the control torque can be expressed as follows:

$$M_c = \frac{K(\theta_1 - \theta_o)}{(1+t_f p)} - \frac{A_3 t_d p M_1}{(1+t_f p)(1+t_d p)}$$

$$M_c = \frac{K(\theta_1 - \theta_o)}{(1+t_f p)} - \frac{A_3 t_d p[(1+t_a p) I p^2 \theta_o / 2 + c p \theta_o]}{(1+t_f p)(1+t_d p)}$$

This gives the complete equation

$$(1+t_a p) I p^2 \theta_o + c p \theta_o = \frac{K(\theta_1 - \theta_o)}{(1+t_f p)} - \frac{A_3 t_d p[(1+t_a p) I p^2 \theta_o / 2 + c p \theta_o]}{(1+t_f p)(1+t_d p)}$$

Figure 9. Dimensionless performance curves and optimum damping parameters for $r = 1.0$

A—*RC*-feedback from generator field current
B—*RC*-feedback from generator armature terminals
C—*RC*-feedback proportional to velocity

RC-Feedb ack Proportional to Velocity $p\theta_o$

For this case the voltage applied from the tachometer motor to the feed-back circuit is given by the equation

$$E_t = g_t p\theta_o$$

$$e_d = \frac{r_d C_d g_t p^2\theta_o}{(1+t_d p)} = \frac{\frac{r_d}{R_d} t_d g_t p^2\theta_o}{(1+t_d p)}$$

The torque term resulting from this voltage is

$$M_d = \frac{-A\frac{r_d}{R_d} t_d g_t p^2\theta_o}{(1+t_f p)(1+t_d p)}$$

The term $A\frac{r_d}{R_d} g_t$ has the dimensions of

$$\frac{\text{torque}}{\text{volt}} \times \frac{\text{volt-seconds}}{\text{radians}} = \frac{\text{torque-seconds}}{\text{radians}}.$$

It also can be expressed by the equation

$$K t_v = A\frac{r_d}{R_d} g_t$$

where K is the stiffness constant of the system, and t_v an arbitrary time constant. Thus

$$M_c = \frac{K(\theta_i - \theta_o)}{(1+t_f p)} = \frac{K t_v t_d p^2\theta_o}{(1+t_f p)(1+t_d p)}$$

and

$$\frac{K(\theta_i - \theta_o)}{(1+t_f p)} - \frac{K t_v t_d p^2\theta_o}{(1+t_f p)(1+t_d p)} = (1+t_a p) I p^2\theta_o + c p\theta_o$$

Synopsis: The basic components of this instrument are

(*a*). A large (35-pound) exciting coil with a pickup coil at its center.

(*b*). An amplifier and integrating circuit.

(*c*). A cathode-ray oscillograph.

The instrument provides a convenient and rapid means of determining the magnetic properties of samples much smaller than can be used conveniently with the ballistic method. Absolute calibration provides greater accuracy and reliability than has been obtained previously in this type of apparatus. Phase errors are reduced to low values through the use of a compensated integrating network with absolute means of adjustment. This network provides a much higher output voltage than the usual circuit and thus makes practicable operation at the power line frequency and the consequent use of an exciting coil of sufficient size to minimize end effect errors and to allow operation at fields as high as 1,000 oersteds for long periods of time.

THIS INSTRUMENT was designed as a research tool in the development of wire for use in magnetic recording and will serve also in connection with process control in the production of this wire. The alloys presently used in the manufacture of recording wire depend on cold working for their magnetic properties, and by measuring these properties at various stages in the drawing process, it is possible to predict the properties of the wire when drawn to the final size. Magnetic measurements on a particular alloy at various diameters in the drawing process, moreover, make possible determining the annealing and drawing schedule required to produce a wire of given magnetic properties.

Of the fundamental magnetic properties in a magnetic recording wire, the residual induction and coercive force seem the most important[1,2] and a recently formed magnetic recording wire standardization committee has set tentative values for these quantities. The equipment for measuring these quantities in the development program of magnetic wire and in the manufacture of this wire must be rugged and simple in operation. It should have sufficient sensitivity to allow measurements on samples consisting of a minimum number of strands of finished wire (0.004-inch diameter). Moderate accuracy is sufficient but the calibrating means should be foolproof and reliable. The cathode-ray oscilloscope hysteresis loop tracer described meets these requirements.

A tester of this same general type but having an operating frequency of ten kilocycles has been in use in the magnetic wire development program at the Armour Research Foundation. Difficulties encountered in the use of this instrument have led to various design improvements in the new tester. Other hysteresis loop tracers of the cathode-ray oscillograph type have been described previously.[2,3]

Experience with the 10-kilocycle tester has shown that, in order to obtain measurements at the intense fields required for saturation of the present magnetic recording wires a much more generously designed field coil would have to be provided. Also, consideration of demagnetizing effects[4] indicated that a much longer magnetizing coil should be used. In the magnetic wire development program, wires as large as 0.040 inch diameter are being studied, and it is these large wires that set the minimum length of the exciting coil.

The size of coil dictated by these two requirements requires for its operation a larger amount of power than can be obtained conveniently from an audio oscillator, and it was this fact that led to choosing the power line frequency as the operating frequency.

Other advantages of this frequency over some higher one are

1. Less trouble caused by stray magnetic fields because all field components are 60 cycles per second (or at most harmonics thereof). Actually it was found practicable to balance out all stray fields with the same device used to balance the air flux in the pickup coil plus a simple phase corrective adjustment.

2. Low stray capacitance effect at low frequency eliminates need for elaborate shielding system.

3. Lower eddy loss in exciting coil makes coil run cooler.

4. Lower reactive component of impedance reduces operating voltage of coil and eliminates need for high voltage insulation. This aids in heat conduction to the coil surfaces and further reduces the temperature rise.

Low operating frequencies in a tester of this type usually impose severe requirements on the amplifier. The gain must be high because the voltage induced in the pickup coil is proportional to the frequency. To keep phase errors small at the operating frequency, the amplifier must have good response at much lower frequencies. The combination of extremely low frequency cutoff and high gain will cause the image on the oscillograph screen to shift up and down with line voltage fluctuations unless special precautions are taken in the design of the amplifier and its power supply.

The severity of these requirements is reduced in the new tester through the use of an improved integrating network which provides at its output terminals a much

higher voltage than the commonly used circuit.

Experience with the 10-kilocycle tester previously used has shown a very definite need for a calibrating system independent of the use of calibrated samples. Long[3] has pointed out the extreme importance of phase errors when an absolute calibration system is used. An analysis of phase errors in the vertical and horizontal systems, and the use of a phase compensating system whose adjustment is made without reference to the shape of the hysteresis trace, has made possible the use of an independent calibrating system in this tester.

Figure 1. Complete test apparatus

Description

The assembled apparatus is shown in Figure 1 and the circuit diagram and list of component parts in Figure 2. The test coils, control panel, and oscilloscope should be spaced approximately as shown in Figure 1 in order to prevent interaction of magnetic fields between the different parts. The oscilloscope is sensitive to the field of the exciting coil and the leakage field of the variable transformer. The effect of the exciting-coil field on the vertical deflection is balanced out when the balancing mutual inductor is adjusted. Perfect compensation of the effect of the variable transformer field is not practicable as both its magnitude and pattern change with the dial setting. There is no provision for balancing the effect of either field on the horizontal deflection, although such compensation could be provided in case space is at a premium. With the present design and with spacings as shown in Figure 1 or greater, the effect of stray fields is small enough to have no appreciable effect on the accuracy of the measurements.

In Figure 3, the six coils arranged around the exciting coil are mutual inductors which serve to measure the peak current and hence the peak magnetizing force in the exciting coil, to balance the air flux in the pickup coil, and to calibrate the B or vertical scale on the oscilloscope. The coils are wound in pairs to allow making fine adjustment of the mutual inductances by varying the distance between two coils of a pair. Each pair is so connected that the vertical components of field are opposite in the two coils. The central plane of the mutual inductors coincides with the center of the exciting coil and their axes are parallel to and at equal distances from the axis of the exciting coil.

With this symmetrical arrangement, the fields of the mutual inductors cancel at the midpoint of the exciting coil and, therefore, calculating the magnetizing force at the center of the exciting coil from its dimensions and ampere turns is made possible. Furthermore, the external field of the exciting coil has no effect on the secondary voltage of a pair of mutual inductors, thus allowing their adjustment before final assembly.

The Exciting Coil

The exciting coil is designed to operate at a peak magnetizing force of somewhat greater than 500 oersteds continuously without exceeding a 55-degree-centigrade temperature rise. The thermal capacity of the winding is sufficient to allow making measurements at 1,000 oersteds providing the variable transformer is run to zero between tests. Measurements on samples at 1,000 oersteds have been made for periods of several hours and it was found that if this precaution is observed the temperature of the coil does not exceed safe limits.

It is desirable to have the magnetic field along the axis of the exciting coil uniform for as long a length as possible. Changes in field strength cause a distribution of magnetic poles along the length of the sample under test, which reduces the induction in the sample because of demagnetizing action.

Figure 4 shows the field distribution in the exciting coil. Data for this curve were obtained by means of a small exploring coil which was connected to a vacuum-tube voltmeter. Voltage readings were obtained with the exploring coil at various positions along the axis of the exciting coil, with the axes of the two coils coinciding, and with a constant 60-cycle current in the exciting coil. The curve shows the field to be constant within 5 per cent over a length of 6.8 inches.

Measurement of Peak Magnetizing Force

A convenient method of measuring the peak current, and therefore the peak magnetizing force, in the exciting coil is the use of a mutual inductor with its primary winding in series with the exciting coil and its secondary connected to a rectifier type voltmeter.[5] In addition to giving a true reading of peak magnetizing force for all wave forms that are likely to be encountered, this method gives an H scale that is almost linear.

To determine the value of mutual inductance giving a convenient scale factor on the H reading voltmeter, it is necessary to know the ratio of instantaneous values of current and magnetizing force in the exciting coil. Two methods for the determination of this ratio are

1. Take simultaneous readings of alternating voltage across an accurately wound pickup coil inside the exciting coil and current in the exciting coil. The accuracy of this method depends on the accuracy to which the dimensions of the pickup coil are known and the accuracy of calibration of the voltmeter and ammeter. Also, the wave form of current, if nonsinusoidal, may affect the accuracy of the ratio determination.

2. Calculate the ratio of magnetizing force to current from the dimensions of the exciting coil.

Method 2 was chosen in the calibration of this tester. The size of the exciting coil allows the determination of its dimensions to a greater percentage accuracy than those of the much smaller pickup coil in the method 1. Also, the wave form errors of method 1 are eliminated.

The H measuring mutual inductor was adjusted to give a scale factor of 10 on a standard 10/100-volt rectifier type voltmeter. Thus two ranges of magnetizing force readings, 100 and 1,000 oersteds full scale, are provided. Because of the linear relation between peak magnetizing force and average voltage, readings are obtained directly from the voltmeter scale.

Calculation of the required value of mutual inductance is given in Appendix I.

Compensation of Air Flux

The induced voltage in the pickup coil is influenced by the flux through the thickness of its winding and in the space inside the coil as well as the flux in the sample Because only that part caused by the ferromagnetic properties* of the sample is of interest, it is necessary to balance all other flux linkages. In previous testers, this has been done by placing a coil similar to the pickup coil near the pickup coil, both being inside the exciting coil. By adjusting the number of turns in the balance coil it is possible to make its voltage the same as that of the pickup coil with no sample in it. By connecting the two coils so that their voltages oppose, the voltage across the two is zero and the air flux in the pickup coil is effectively balanced out. The balancing operation is a very tedious one as it must be performed with great accuracy because of the large ratio of air flux to sample flux.

In order to provide for an external balance adjustment and to prevent restriction of air circulation on the inside of the exciting coil caused by the presence of an extra coil beside the pickup coil, balancing on the new tester is accomplished by means of an adjustable mutual inductor.

The behavior of the exciting and pickup coils, less sample, is that of a mutual inductor. To balance the air flux, therefore, it is merely necessary to connect a mutual inductor with its primary in series with the exciting coil and the secondary in series-opposing with the pickup coil. If the two mutual inductances are of the same value, the net secondary voltage should be zero.

The required value of mutual inductance was calculated from the dimensions and number of turns in the exciting and pickup coils. The balancing mutual inductor was designed for a somewhat higher value and then trimmed down by removing primary turns. The final balance adjustment is obtained by varying the spacing of the two halves of the mutual inductor.

When the final balance was first attempted, it was found that a residual net voltage of 0.025 volt could not be eliminated by adjustment of the mutual inductor. This minimum residual voltage was obtained with a magnetizing force of 500 oersteds in the exciting coil, and at the same field the voltage across the secondary of the balance coil was only 24.5 volts. The residual voltage was found to be a sine wave of 60 cycles per second and, therefore, was caused by a very slight phase shift (0.058 degree) between pickup and balance coil voltages.

This phase difference is caused by a small amount of mutual resistance which is present in different amounts in the two sets of coils. Mutual resistances are caused by eddy currents in the winding conductors and clamping bolts, which set up spurious magnetic fields having components out of phase with the primary current. These out-of-phase field components induce voltage components in the secondary circuit which are in phase with the primary current.

Although the phase difference caused by these mutual resistances is extremely small, the resulting residual voltage is large enough to affect seriously the accuracy of measurement on small samples.

The residual voltage was eliminated through the use of the mutual resistance coils placed near the ends of the pickup coil (see Figure 5). These coils, when connected across a variable resistance, increase the mutual resistance between the exciting coil and the pickup coil.

When the balancing mutual inductor and the variable resistance are adjusted properly, no residual voltage is detectable with amplifier gain and vertical gain on the oscillograph at maximum. Under this condition 0.0005 volt or greater would be detected.

Integrating Network

The net induced voltage in the pickup and balance coils is proportional to the time rate of change of flux in the sample. As it is desired that the vertical deflection of the oscilloscope beam be proportional to the flux, rather than its derivative, it is necessary to integrate the signal before it is applied to the oscilloscope.

Figure 3. Test coils with upper clamping plate removed

A series combination of a resistor and capacitor with the input across the end terminals and the output across the capacitor will integrate satisfactorily providing the reactance of the capacitor at the lowest frequency of interest is very small compared to the series resistance. This makes the ratio of output to input voltage very small. For instance, if the phase error of the network is to be held to $^1/_2$ degree at the lowest frequency, the output voltage will be only $^1/_{118}$ of the input voltage at this frequency.

A characteristic of this simple circuit is that the phase error will be greatest at the lowest (fundamental) frequency and will be less for the harmonics. It would seem desirable that the reverse be true because, in general, phase errors in the fundamental frequency are of the greater importance.

The integrating network used in the new tester provides a much higher voltage at its output terminals than the simple series circuit and gives zero phase error at the fundamental frequency with slight errors at the harmonic frequencies. The magnitude of these errors at harmonic frequencies depends on the values of capacitances and resistances used in the network, and becomes less as the ratio of output to input voltage is made less.

The integrating network used in the tester is shown schematically in Figure 6. R_e represents the effective output resistance of amplifier stage V_1 in Figure 2. Capacitors C_2, C_3, and C_4 in Figure 2 are shown as C_c, C_b, and C_a in Figure 6. R_b replaces R_{10} and R_{11}.

With the constants chosen in the tester, the phase error is zero at the fundamental frequency (60 cycles per second), 0.3 degree at the third harmonic, and less than this amount for all higher order harmonics. The error in relative magnitude for the fundamental and all harmonics is about 3.5 per cent. The ratio of output to input voltage at the fundamental frequency is 1 to 16.8. An integrating network of the simple series type providing the same voltage ratio would have a phase error of 3.4 degrees at the fundamental frequency.

The steep sides on a hysteresis loop for a sample at saturation correspond to relatively high voltage peaks of very short duration in the pickup coil. Therefore, moderate phase errors in the vertical deflection system may cause serious errors in the location and slope of the sides of the loop with corresponding errors in the coercive force and residual magnetism readings. Moderate phase errors also may cause the appearance of loops at the tips of the pattern on the oscilloscope, but absence of these loops is not an indication that the phase relations for the fundamental and all harmonics are not sufficiently in error to cause serious errors in the readings.

In an instrument having built-in calibration, therefore, it is important to have a phase check other than merely observing the trace on the oscilloscope. This means is provided in the calibration of the instrument (see Appendix III).

A complete analysis of the integrating circuit used in the tester is given in Appendix II.

Figure 4. Field distribution along axis of exciting coil

Preamplifier for Vertical Deflection System

The frequency range of the vertical and horizontal amplifiers contained in the oscilloscope used with the tester is from 2 to 100,000 cycles per second. Measurements on the vertical and horizontal systems showed the phase characteristics to be entirely satisfactory. Using these self-contained amplifiers simplifies the design of the equipment external to the oscilloscope.

V_1 in Figure 2 amplifies the signal from the pickup circuit. Its effective output impedance serves as the series resistor feeding C_2, C_3, C_4, R_{10}, and R_{11} of the integrating network.

V_2 is connected as a cathode follower and allows the integrating network to feed into a high impedance (four megohms). This is necessary for proper operation of the integrator. This high value of grid resistor also minimizes the phase error introduced by coupling capacitor C_5. For the values chosen, the phase error is 0.38 degree at 60 cycles per second.

A coupling capacitor to the input stage in the oscilloscope is provided in the oscilloscope so it is possible to feed the voltage across R_{12} (which includes a d-c component) directly to the input terminals.

Cathode by-pass capacitors are omitted in order to eliminate phase errors from this source.

R_6 serves as an input attenuator for the preamplifier. The control is usually set at maximum and the vertical calibration is obtained by adjusting the gain control on the oscilloscope. In testing large samples, V_1 may overload with maximum setting on R_6, and in such cases the R_6 setting should be reduced and the oscilloscope gain setting increased. This procedure is also necessary in testing small samples of relatively high permea-

Figure 5. Detail of sample holder

bility material at beyond saturation excitation conditions. Because of steep sides of the hysteresis loop in such cases, the peak voltage applied to the input of the preamplifier is much higher than would be expected from the height of the oscilloscope pattern.

The extremely low cutoff frequency of the vertical deflection system causes slow variations in the plate supply voltage (such as would be caused by line voltage variations) to be amplified and fed to the vertical deflection plates of the oscilloscope. The result is instability of the position of the hysteresis trace on the screen. The problem is made especially severe because of the action of the integrator which inherently has increasing response with decreasing frequency.

In order to limit these voltage variations to a low value, the self-regulating power supply shown in Figure 2 (lower center) is used. When first built, a glow tube was used for the reference voltage, but the stability of the system was improved when the glow tube was replaced by the 90-volt battery. Since V_1 operates with a negative grid bias the life of this battery should be its shelf life.

There is still some instability of the pattern. Attempts to improve the situation through the use of a constant voltage transformer supplying the power supply of the preamplifier and the oscilloscope resulted in no improvement. With the apparatus in its present form, the pattern is sufficiently stable to allow making measurements on small samples with both R_6 and the vertical gain on the oscilloscope set at maximum. Some trouble may be encountered, however, in taking pictures unless short exposure times are used.

Figure 6. Schematic diagram of integrating network

Calibrating System for Vertical Deflection

Calibration of the vertical system is accomplished by means of the H meter (M in Figure 2) and the calibrating mutual inductor CM. The measure-calibrate switch S_2 removes the calibrating system from the circuit when in the "measure" position. Two calibrating ranges are provided by means of the 100/1 voltage divider (R_2, R_3, and R_4). The capacitor C_1 across R_2 and R_4 corrects for a slight phase error in the voltage divider.

The calibrating mutual inductor was designed and adjusted to give the calibrating formulas

$$H_{cal} = 2a'' B_{cal} \times 10^{-8} \qquad (1)$$

for the "low calibration" position, and

$$H_{cal} = 2a'' B_{cal} \times 10^{-8} \qquad (2)$$

for the "high calibration" position

B_{cal} is the value of B in gausses to be calibrated
a'' is the area of the sample in circular mils
H_{cal} is the required reading of the H meter in oersteds

Sinusoidal wave form of the calibrating current is not required for accurate calibration with the method used in the tester. This is shown in Appendix III, which gives a complete analysis of the calibrating system.

Operation of the Tester

Sensitivity of B and H Scales

With the input attenuator in the preamplifier and the oscilloscope vertical gain control both at maximum, the total vertical deflection (up and down) is 2.56 inches per maxwell. Thus on a single strand of 0.004-inch diameter wire having a saturated residual magnetism of 2,000 gausses (typical for the presently used magnetic recording wire) the height of the hysteresis loop would be about 0.4 inch. This deflection is sufficient for rough measurements but if the full accuracy of the instrument is to be realized, five or more strands of the finished wire should be used. If characteristics of the wire at low inductions are being studied, an even greater number of strands should be used. The opening in the sample holder is large enough to allow the use of 100 strands of the 0.004-inch wire.

With the horizontal gain on the oscilloscope at maximum, the sensitivity of the horizontal system is 0.0129 inch (total left and right) per oersted.

Balance and Phase Adjustment

The balance adjustment is made with no sample in the tester. With the magnetizing force set at about 500 oersteds, and with both vertical gain controls set at maximum, the horizontal gain on the oscilloscope is adjusted to give a pattern about one half of an inch wide. With S_2 in the "measure" position, the position of one of the balancing mutual inductor coils is adjusted to give a pattern of minimum height. If this pattern is an ellipse, the mutual resistance adjustment is varied until a line pattern is obtained. If the line is not horizontal, further simultaneous adjustments of the balance coil and the mutual resistance control are made until a horizontal line pattern is obtained. This completes the balance adjustment.

The phase adjustment is made with the magnetizing force set at 500 oersteds and with no sample in the tester, as before. With S_2 in either of the calibrating positions, and with the horizontal gain control at maximum, the vertical gain controls are adjusted to give a 45-degree pattern. If the "high calibration" setting is used, the B gain control on the control panel must be kept at a low setting to prevent overloading of the preamplifier. If the pattern is an ellipse, the phase adjustment is reset so as to make it a line. This completes the phase adjustment.

Calibration of H and B Scales

The H meter at all times indicates the peak magnetizing force in oersteds in the exciting coil. The calibration of the H scale is accomplished simply by adjusting the horizontal gain control to give a total horizontal deflection equal to the reading

Figure 7. Preamplifier and power supply

of the H-meter divided by a convenient scale factor. This adjustment may be made with or without a sample in the tester.

The B scale calibration is made with no sample in the tester and after the balance and phase adjustments have been made. For small samples of low permeability the "low calibration" position is used, and for larger sample or samples of high permeability "high calibration" is used. Equations 1 and 2 give the relation between the reading of the H meter and the value of B to which the resulting total vertical deflection on the oscilloscope corresponds.

For routine tests on samples whose properties are known approximately, the instrument is precalibrated by adjusting the vertical gain so that a convenient scale factor is obtained. This method allows obtaining the magnetic properties directly from observed deflections on the screen.

For odd samples of unknown properties it is more convenient to calibrate after deflections are measured on the hysteresis loop. This method requires the use of equations 1 or 2 in calculating actual B vulues from the deflections.

In order to prevent excessive errors caused by nonlinearity between oscilloscope deflections and applied voltages, the B and H scales should be calibrated at values near the expected values for the sample. As the residual magnetism and coercive force are usually of most interest, the B and H calibrations should be performed near the expected values of these quantities.

The balance, phase, and calibration adjustments should be checked at frequent intervals to guard against errors resulting from drift or accidental change of adjustment.

Preparation of Samples

To prevent errors caused by self-demagnetization and to allow convenient insertion in the sample holder, samples are cut to a length somewhat greater than the length of the exciting coil (about 15 inches). Samples of finished recording wire are "fished" into lengths of small spaghetti tubing which provide stiffness. Larger samples having sufficient stiffness are put directly into the sample holder. If it is desired to study the variations over a great length of wire, the wire may be threaded through the sample holder. Readings from the hysteresis loop may then be obtained as the wire is pulled through the tester.

Limitations of the Tester

The apparatus was designed specifically for use with the stainless steel wires presently used in magnetic recorders. These alloys have their maximum permeabilities (ranging up to about 15) at about 350 oersteds. The carbon steel wires used in older machines have maximum permeabilities as high as 280 at about 50 oersteds. When these high permeability wires are tested too far above saturation, the hysteresis loop shows evidence of distress. The pickup coil is set into self oscillation and the preamplifier may overload even with the preamplifier gain set at a low value.

The tendency for self-oscillation was reduced by replacing the shielded leads originally used in the pickup circuit by a low capacity line (see Figure 5). This line consists of two number 30 wires spaced about one-quarter inch. Of various filter schemes that were tried, several were successful in eliminating the oscillations but unfortunately yielded coercive readings that were too high. The effect of these filters was to slope off the steep voltage peaks associated with the almost vertical sides of a hysteresis loop at beyond saturation. These filter schemes therefore were discarded as their use would only lead to false confidence in beautiful hysteresis loops at intense fields.

With the apparatus in its present form, the high permeability samples may be tested at sufficiently intense fields to assure saturation, without overloading or self-oscillation difficulties. This is evident from Figure 13.

When high permeability samples are being tested, the vertical gain control on the oscilloscope should be set at maximum and calibration achieved by means of the preamplifier gain control. This will reduce to a minimum the possibility of overloading the preamplifier.

Accuracy

Four samples of widely different magnetic properties were tested in the 60-cycle hysteresis loop tracer and then by means of the familiar d-c method employing a ballistic galvanometer for the induction measurements. Each of the samples consisted of 100 strands of 0.004-inch diameter magnetic recording wire about 16 inches long enclosed in a piece of small spaghetti tubing. To eliminate errors caused by varying sensitivity of the oscilloscope over different regions of the screen, the system of calibrating after the measurement was used. The procedure was to adjust the vertical and horizontal gain controls so that the intercepts of the trace on the vertical and horizontal axes (corresponding to the residual induction and the intrinsic coercive force) were at convenient points on the screen. Then with the sample removed, and with the gain controls undisturbed, the magnetizing force was adjusted to a value providing a horizontal line trace on the screen

whose length was equal to the distance between the intercepts on the horizontal axis of the hysteresis loop. This value of magnetizing force is the intrinsic coercive force for the sample Then, with the switch in one of the calibrating positions, and with the horizontal gain control at zero, the magnetizing force was adjusted to provide on the oscilloscope a vertical line trace whose length was equal to the distance between the intercepts of the hysteresis loop on the vertical axis. The value of residual induction for the sample was obtained by substituting in equation 1 or 2 the area of the sample for a'', the value of magnetizing force determined for H_{cal}. This value of B_{cal} is the residual induction for the sample. Values of maximum induction were obtained by reducing the horizontal gain control to zero and adjusting the vertical gain to provide a vertical line pattern of a convenient length. Then with the sample removed, with the switch in one of the calibrating positions, and without disturbing the gain controls, the magnetizing force was adjusted to provide a vertical line pattern of the same length as before. Substitution of this value of magnetizing force for H_{cal} in equation 1 or 2 gave the value of maximum induction for the sample.

The coil assembly of the a-c tester was used in the d-c ballistic method. The balancing mutual inductor was used to balance the air flux in the pickup coil just as in the a-c method. Calibration of the ballistic galvanometer was accomplished by means of the calibrating mutual inductor. The source of power was a bank of storage batteries. The usual arrangement of switches and rheostats for reversing and controlling the currents in the measuring and calibrating circuits was provided.

The currents in the exciting coil and in the primary circuit of the calibrating mutual inductor were measured by means of ammeters with a guaranteed accuracy of one-half of one per cent of full scale. Values of magnetizing force and galvanometer sensitivity were obtained from these ammeter readings.

With the a-c instrument as described in this paper the accuracy of both induction and magnetizing force calibrations is dependent on the accuracy of the rectifier type voltmeter on the panel. This instrument had been calibrated and provided with a direct reading magnetizing force scale several months prior to the running of the accuracy test. Immediately before running the accuracy test, the calibration of this instrument was rechecked and was found to be in error by a maximum of two per cent of full scale value at certain parts of the scale. In the lower range of the scale, errors in magnetizing force and in the calibration of the induction scale on the oscilloscope could be in error by as much as eight per cent because of this error in calibration of the panel voltmeter.

In order to separate this voltmeter error from other errors, the a-c measurements first were made by relying on the panel voltmeter for all readings and calibrations, and then repeating the measurements with the current in the exciting circuit being measured with a current transformer and a dynamometer type ammeter with a guaranteed accuracy of one quarter of one per cent of full scale. In this case the calibrations were based on the readings of this ammeter. With this method, variations in the wave form of current from a sine wave may cause errors, as the ammeter is sensitive to the rms value while the oscilloscope calibration depends on the peak value of current. The ratio of these values was taken to be the square root of two, the value for a sine wave. It is believed that errors resulting

B_r = residual induction, gausses
B_{mi} = maximum intrinsic induction, gausses

from this assumption are very small, as harmonics in the current caused by harmonics present in the supply voltage are virtually suppressed by the high inductive component of impedance in the magnetizing circuit. Furthermore, the voltage wave form of the 60-cycle power source itself is very nearly sinusoidal.

Results of the comparative measurements are given in Table I.

Samples 192, 219, and 702 are stainless steel magnetic recording wire. Sample 703 is medium carbon steel magnetic recording wire.

Comparison of the d-c ballistic measurements with the a-c measurements based on the panel voltmeter show discrepancies up to nine per cent for induction readings and ten per cent for intrinsic coercive force readings. The maximum discrepancies shown by a comparison of the ballistic measurements with the a-c measurements based on the current transformer and ammeter are 2.7 per cent for induction values and 2.3 per cent for intrinsic coercive force values.

Some errors are common to both the a-c and the ballistic methods and therefore would not be detected by the comparison.

1. *Ratio of magnetizing force to current in exciting coil.* This ratio was assumed to be the same for the a-c and the ballistic measurements and was based on equations 3 and 4 of Appendix I. For a coil of proportions similar to those of the exciting coil, large percentage errors in individual values of b, c, d, and D have a very small effect on the calculated value of K in equation 4. The accuracy of the determination of the ratio of magnetizing force to current is therefore essentially dependent on the accuracy with which the quantity N/b (turns per unit length) is determined. As this value was based on the average of the layer lengths, each of which was determined to an accuracy of at least one-half of one per cent, the probable error in N/b and, therefore, in the ratio of magnetizing force to current is less than one-half of one per cent.

2. *Calibration of mutual inductor.* The sensitivity of the bridge used in adjusting the mutual inductors was sufficient to detect a change in mutual inductance of less than one-tenth of one per cent. The calculated value of mutual inductance depends on the product of two resistances and one capacitance. Calibration of the corresponding components in the bridge is accurate to one-tenth of one per cent for each. Calibration of the mutual inductor therefore is accurate to less than one-half of one per cent.

3. *End effect.* Figure 4 shows that the magnetizing force in the exciting coil at points three inches from the center is about four per cent less than the value at the center. Demagnetizing effects were estimated on the assumption of a sample six inches long in a uniform field. It is quite evident that demagnetizing effects in this hypothetical case are more severe than in the actual case in which the sample extended beyond the ends of the exciting coil, the magnetizing force of which is only four per cent low at three inches from the center and gradually decreases to about one-half value at the ends. Maxwell's equation for the demagnetization factor for an ellipsoid was used in calculating the demagnetizing factor for the assumed 6-inch long sample. The ratio of length to diameter was taken as 6 inches divided by 0.040 inches (diameter of a solid wire having the same cross-sectional area as 100 strands of 0.004-inch diameter wire). That this assumption is also a conservative one is evident from the following considerations.

If the 100 pieces of wire comprising the sample were placed in and parallel to a uniform field with sufficient spacing between wires that for every wire the demagnetizing effect due to poles on the remaining wires is negligible, then the demagnetizing effect on the group of wires would be the same as that on a single wire. If the distance between wires then were decreased gradually, the demagnetizing effect would increase continuously, because of the increasing demagnetizing action on every wire caused by decreasing separation between it and poles on adjacent wires. The demagnetization effect would have for its limiting value that corresponding to the condition in which the wires are pressed together to form a single solid wire. If the pressing operation were performed in such a manner as to keep the lengths of the strands unchanged, the cross-sectional area of this wire would be equal to the sum of the cross-sectional areas of the individual wires. Therefore, the demagnetizing factor for a sample made up of parallel strands is less than that for a solid sample of the same cross-sectional area and decreases as the distance between strands increases.

The demagnetizing effects are most severe in sample 703 because of its higher maximum intrinsic induction. On the basis of the demagnetizing effects calculated in accordance with the above assumptions, the actual magnetizing force present at the center of the sample is 3.7 oersteds less than the value at the same point in the solenoid with the sample removed. This amount of change in magnetizing force near saturation will have an insignificant effect on the intrinsic induction.

The calculated reverse field caused by the residual induction in this sample is 2.5 oersteds. The hysteresis loop for this sample is similar to the one shown in Figure 13. Examination of this figure shows that a reverse field of 2.5 oersteds causes a reduction of 250 gausses from the residual induction value and the error in the residual induction reading due to the demagnetizing effect is about two per cent. For a 10-strand sample of this material, the number ordinarily used in the hysteresis loop tracer, the effect of demagnetization on the residual induction reading would be entirely negligible.

Measurements of intrinsic coercive force are unaffected by demagnetization, because when the intrinsic induction is zero the intensity of magnetization is zero and there are no poles in the sample.

As a check on the various assumptions upon which the calculation of demagnetization effects was based, sample 703 was cut into lengths of one to five inches, inclusive. The value of indicated maximum magnetizing force required to produce an intrinsic induction of 11,300 gausses (the value for maximum susceptibility) was determined for each length by measurement in the a-c tester. The effective magnetizing force was calculated first on the basis of an effective diameter of 0.040 inch, then on the basis of a diameter 1.15 times this value and finally a diameter $^1/_{1.15}$ of this value by deducting from the

Figure 11. Hysteresis loop for stainless steel wire intermediate in drawing process

Figure 12. Hysteresis loop for finished stainless steel wire

measured magnetizing forces the corresponding computed values of demagnetizing forces. Results of these measurements and calculations appear in Table II.

For sample lengths approaching the length of the pickup coil, there is an error in induction readings caused by fringing of flux near the ends of the sample. Incomplete linkage of the wire flux with the pickup coil causes measured values of induction to be less than actual values at the center of the sample. Therefore, while the magnetizing force was adjusted for an indicated maximum intrinsic induction of 11,300 gausses for each length, the actual induction for the short samples was greater than this amount. As no correction was made for this error, and as its effect is to make magnetizing force readings too high for the short samples, magnetizing force readings corrected for demagnetization only should increase as the length of the sample approaches that of the pickup coil. In no case should the corrected value decrease as the sample length is decreased.

In Table II the data corrected on the basis of 0.040-inch effective diameter are the same for the 5-inch, 4-inch and 3-inch samples within the limits of experimental error. Data for the 2-inch and 1-inch lengths are high because of the linkage error discussed before.

The data based on the 0.046-inch effective diameter are low at three and two-inches by amounts definitely greater than experimental error. The only explanation of these low values is incorrectness of the assumption of 0.046-inch effective diameter.

Although the data based on the 0.0348-inch effective diameter show continuously increasing values as the sample length is decreased, values for the 5-inch, 4-inch, and 3-inch lengths differ by amounts less than experimental error.

It therefore cannot be concluded from the data whether the 0.040-inch or the 0.0348-inch diameter is more nearly correct. It is definitely shown, however, both by experiment and by the previous analysis, that actual demagnetizing effects in a bundle of wires are less than or equal to the effects as calculated on the basis of an area-equivalent solid wire. The experimental data further show that the true effective diameter for a tight bundle of wires is only slightly less than that of the area-equivalent solid wire. (If experimental errors are neglected, an equivalent diameter about 0.92 times that of the area-equivalent solid wire is indicated.)

Calculations on this basis show that for low permeability materials (for which the tester was designed primarily) no correction need be made for demagnetizing effects. For materials of higher permeability than about 300, demagnetization effects may be calculated as described and if the effects are appreciable corrections may be applied as was done for sample 703.

In Table I discrepancies between the a-c measurements with the current transformer and ammeter and the d-c ballistic measurements are of the order that would be expected in the ballistic method from changes in currents subsequent to their adjustment, due to heating of the rehostats and voltage regulation in the batteries. Actually it was found that in repeating tests under identical conditions, discrepancies on a percentage basis were lower with the a-c method than with the ballistic method.

From these considerations it is evident that errors in measurements on the hysteresis loop tracer are almost entirely due to errors in reading distances on the oscillograph screen, and to errors in the instrument used to measure the peak current in the magnetizing circuit. If the gain controls are adjusted so that the distances being measured on the screen are of the order of three inches, and if reasonable care is taken in measuring the distances, they can be determined to an accuracy of about two per cent.

With the tester as described in this paper it is sometimes necessary to take readings low on the scale of the panel voltmeter. In these cases errors as high as 20 per cent are possible because of reading errors and changing characteristics of the rectifier in the instrument. This error could be reduced to about ten per cent by providing more scales on the instrument.

It is believed that while the combination of a mutual inductor and a rectifier type voltmeter provides a measuring device sensitive to peak currents, greater over-all accuracy would be obtained if the magnetizing current were measured by means of current transformer and ammeter sensitive to rms values (assuming an essentially sinusoidal supply voltage). Panel instruments of this type are available with a guaranteed accuracy of one per cent of full scale. If a current transformer with taps providing full scale ranges of 100, 200, 500, and 1,000 oersteds is used, the maximum error in any current reading need be no more than 2.5 per cent, and magnetic readings to an accuracy of about 5.0 per cent are possible. It is planned to make this change in the instrument.

Results Obtained With the Hysteresis Loop Tracer

Figures 9 and 10 are two of a series of curves that were obtained to compare the recording characteristics of stainless steel and carbon steel wires.

In obtaining these data, ten strands of 0.004-inch diameter recording wire were used. To facilitate comparison of the shapes of the curves, arbitrary gain settings making the B_r deflections the same for all samples at the highest magnetizing force were used. Deflections in tenths of an inch are plotted on the graphs. The vertical scale factors, also shown, allow calculating actual B_r values from the curves.

Photographs of hysteresis loops for various samples are shown in figures 11 to 15 inclusive. Figure 11 shows the loop for a sample of stainless steel recording wire intermediate in the drawing process. The remaining loops are for finished wires. Figures 13 and 14 are for the same sample at different magnetizing forces. A state of near saturation at the

lesser field is shown by a comparison of the two figures.

Evidence of oscillation in the pickup coil is beginning to appear in the loop for the greater field. These hysteresis loops were obtained with the vertical gain control in the oscilloscope set at maximum, and the control at the input to the preamplifier at a low value. This setting tends to prevent overloading of the preamplifier.

Figure 16 shows evidence of this overloading. This curve was obtained with the same sample and with the same magnetizing force as in figure 14 but with the gain setting on the preamplifier increased and that on the oscilloscope decreased.

Conclusions

The convenience of obtaining measurements from the hysteresis loop on a cathode-ray oscillograph screen has made this general type of apparatus a very useful tool in magnetic measurements when large numbers of samples must be tested. Use of an absolute calibration system and a phase-compensated integrating network with positive means of adjustment has made possible a degree of accuracy and reliability higher than has been possible previously with this general type of apparatus.

Errors in the tester as described are due mainly to inherent errors in the rectifier type voltmeter used to calibrate the vertical and horizontal deflection systems. While in some cases the resulting errors in magnetic readings may be as high as 20 per cent, in most cases they are limited to about five per cent.

Replacement of the rectifier type voltmeter and its associated mutual inductor by a current transformer and ammeter will make possible magnetic readings with a consistent accuracy of five per cent, providing the wave form of the power line voltage is essentially sinusoidal.

In selecting the power line frequency as the operating frequency for the tester the advantages of this and some higher frequency were compared carefully. Some of the more important items of comparison are

A. In favor of a higher frequency

1. Greater volts per turn in pickup coil.

2. If the frequency is near the logarithmic mean of the audio band, materials for use in audio frequency apparatus will be tested more nearly under conditions of use.

3. Greater simplicity of amplifiers and their power supplies.

4. Lower spurious voltages induced by fields of the power line frequency.

B. In favor of the power line frequency

1. Practically unlimited power available without the use of oscillators or motor generator sets—especially important when intense fields are required.

2. Conditions of test more nearly approximate those of the ballistic method. (The truly basic magnetic characteristics of a material are those determined by the ballistic or other d-c method.)

3. Greater number of turns permissible in pickup coil because of lesser effect of distributed capacitance at low frequencies. (*A*–1 is balanced, at least in part, by this consideration.)

4. The two sources of spurious voltage—that caused by stray fields from transformers in the amplifier power supply and from nearby power wiring, and that caused by interaction of the different circuits of the tester at the operating frequency—are both of the same frequency. This fact simplifies the problem of balancing the spurious voltages. (In the tester the air flux balance coils and the mutual resistance adjustment are sufficient in themselves to reduce all residual voltages to negligible values.) If the operating frequency were other than the power frequency, separate adjustments would very likely be required for balancing the effects of the two sources of spurious voltage.

5. Conveniently low operating voltage for the exciting coil without excessive eddy loss in the winding. (If the exciting coil in the tester were operated at 500 cycles per second, the terminal voltage would change from 130 volts to 1,080 volts, and the change in eddy loss would be sufficient to cause a significant increase in power requirements and temperature rise.)

Figure 14. Hysteresis loop for carbon steel wire at 500 oersteds

Appendix I. Calculations for Peak Magnetizing Force Measuring System

Integration along the axial direction and perpendicular to this direction in turn shows the magnetizing force at the center of a solenoid to be

$$H = 0.4\pi K_s\left(\frac{N}{b}\right)i_p \tag{3}$$

where

$$K_s = \frac{b}{2c}\left[\sinh^{-1}\left(\frac{D}{b}\right) - \sinh^{-1}\left(\frac{d}{b}\right)\right] \tag{4}$$

i_p = instantaneous current in amperes

$\left(\frac{N}{b}\right)$ = turns per centimeter of length

D = outside diameter of the coil

d = inside diameter

b = length

c = thickness

H = instantaneous value of magnetizing force in oersteds at the center of the solenoid

The ratio of magnetizing force to current is therefore

$$\frac{H}{i_p} = 0.4\pi K_s\left(\frac{N}{b}\right) \tag{5}$$

or with (N/b) in turns per inch equation 5 becomes

$$\frac{H}{i_p} = 0.495K_s\left(\frac{N}{b}\right) \tag{6}$$

K_s is independent of the dimensions used because only ratios are involved in its determination.

Let the henrys mutual inductance of the H measuring mutual inductor be M_h. If a periodic current having equal positive and negative peaks and which never decreases in the time from negative peak to positive peak nor increases in the time from positive peak to negative peak flows in the primary winding of the mutual inductor, the secondary voltage is given by

$$e_s = M_h\frac{di_p}{dt} \tag{7}$$

where e_s and i_p are instantaneous values of secondary voltage and primary current, and t is time in seconds.

For the time from negative peak to positive peak

$$E_a' = \frac{1}{t}\int_0^{t_1} e_s\,dt \tag{8}$$

where t_1 is the time from negative peak to positive peak, and E_a' is the average secondary voltage over this time.

Substituting equation 7 in equation 8 and remembering that when $t=0$, $i_p=-I_m$ and when $t=t_1$, $i_p=I_m$; where I_m is the absolute value of positive and negative peaks

$$E_a' = \frac{M_h}{t_1}\int_{-I_m}^{I_m} di_p = \frac{2M_h}{t_1}I_m \tag{9}$$

Similarly, for the time from positive peak to negative peak the avera gesecondary voltage is

$$E_a'' = -\frac{2M_h}{t_2}I_m \tag{10}$$

where t_2 is the time from positive peak to negative peak.

The average of the absolute value of volt-

age over a cycle, or any number of complete cycles, is

$$E_a = \frac{E_a' t_1 + |E_a'' t_2|}{t_1 + t_2} = \frac{4M_h I_m}{t_1 + t_2} \tag{11}$$

or, as $\frac{1}{t_1+t_2} = f$ the frequency in cycles per second

$$E_a = 4M_h f I_m \tag{12}$$

Rectifier type voltmeters are regularly calibrated to read the rms value of a sine wave, or $\pi/2\sqrt{2}$ times the average of a wave of any form. Therefore, the reading of such a voltmeter connected to the secondary of the mutual inductor will be

$$E_v = \frac{\pi}{2\sqrt{2}} E_a = \frac{\pi}{2\sqrt{2}} 4M_h f I_m \tag{13}$$

For a scale factor of 10 on the H meter

$$E_v = \frac{H_m}{10} \tag{14}$$

where H_m is the peak magnetizing force in oersteds in the exciting coil.

Substituting equation 14 in 13 and solving for M_h and replacing H_m/I_m by H/i_p

$$M_h = \frac{\sqrt{2}}{20\pi f}\left(\frac{H}{i_p}\right) \tag{15}$$

Substitution of the measured dimensions for the exciting coil in equations 4 and 6 gave

$$\frac{H}{i_p} = 44.2 \tag{16}$$

The required value of M_h therefore is

$$M_h = \frac{\sqrt{2}}{20\pi 60} \times 44.2 = 16.57 \times 10^{-3} \text{ henry} \tag{17}$$

The H measuring mutual inductor was designed for somewhat greater than this value and then adjusted to this value by removing primary turns and, finally, by adjusting the relative position of the two parts of the inductor. A modified Carey Foster bridge[5] was used in making this adjustment.

Appendix II. Analysis of Integrating Network

In Figure 16, C_a, C_b, and R_b may be thought of as a corrective network for the simple series integrator, C_c and R_c, which by itself introduces a serious error at the fundamental frequency due to its small time constant. Actually, however, C_a and C_b add to the capacitance of C_c and serve to increase the time constant as well as serving as a corrective network.

In this network C_a, C_b, and C_c are chosen equal so we may write

$$C_a = C_b = C_c = C \tag{18}$$

and

$$Y_c = Y_a = Y = j\omega C \tag{19}$$

If the network is loaded by an impedance that is very high compared to the reactance of C_a at the lowest frequency, the currents may be represented as shown in Figure 16.

$$i_2 = e_1 Y \tag{20}$$

$$e_2 = e_1 + i_2 Z = e_1 + e_1 YZ \tag{21}$$

$$i_1 = e_2 Y = e_1 Y + e_1 Y^2 Z \tag{22}$$

$$i_1 + i_2 = e_1 Y + e_1 Y^2 Z + e_1 Y = e_1 Y(2 + YZ) \tag{23}$$

$$e_3 = e_2 + (i_1 + i_2) R_c = e_1 + e_1 YZ + e_1 Y(2 + YZ) R_c \tag{24}$$

$$\frac{e_3}{e_1} = 1 + YZ + YR_c(2 + YZ) = 1 + YZ + 2YR_c + YZYR_c \tag{25}$$

Substituting

$$Y = j\omega C$$

and

$$Z = \frac{R_b(1 - j\omega CR_b)}{1 + \omega^2 C^2 R_b^2}$$

$$\frac{e_3}{e_1} = 1 + \frac{R_b(\omega^2 C^2 R_b + j\omega C)}{1 + \omega^2 C^2 R_b^2} + j2\omega CR_c + \frac{R_b(-\omega^3 C^3 R_c^2 + j\omega^3 C^3 R_b R_c)}{1 + \omega^2 C^2 R_b^2} \tag{26}$$

Separating real and imaginary terms

$$\text{Real } \frac{e_3}{e_1} = 1 + \frac{R_b(R_b - R_c)\omega^2 C^2}{1 + \omega^2 C^2 R_b^2} \tag{27}$$

$$\text{Imaginary } \frac{e_3}{e_1} = j\omega C\left[R_b \frac{1 + \omega^2 C^2 R_b R_c}{1 + \omega^2 C^2 R_b^2} + 2R_c\right] \tag{28}$$

Equations 27 and 28 rearranged in terms of ωCR_b and R_c/R_b become

$$\text{Real } \frac{e_3}{e_1} = 1 + \frac{(\omega CR_b)^2}{1 + (\omega CR_b)^2}\left(1 - \frac{R_c}{R_b}\right) \tag{29}$$

Figure 15. Hysteresis loop for carbon steel wire showing distortion caused by improper adjustment of gain controls

Figure 16. Diagram for analysis of integrating network

$$\text{Imaginary } \frac{e_3}{e_1} = j\omega CR_b\left[\frac{1 + (\omega CR_b)^2 \frac{R_c}{R_b}}{1 + (\omega CR_b)^2} + 2\frac{R_c}{R_b}\right] \tag{30}$$

For perfect integration e_3/e_1 should have no real component, and the error angle θ is given by

$$\theta = \tan^{-1}\left[\frac{\text{real } \frac{e_3}{e_1}}{\text{imaginary } \frac{e_3}{e_1}\frac{1}{j}}\right] \tag{31}$$

Providing θ is not too large

$\left|\frac{e_3}{e_1}\right|$ is given with sufficient accuracy by

$$\left|\frac{e_3}{e_1}\right| = \text{imaginary } \frac{e_3}{e_1}\frac{1}{j} \tag{32}$$

For perfect integration $\left|\frac{e_3}{e_1}\right|$ should vary inversely with ω, or

$$\frac{1}{\omega CR_b}\left|\frac{e_3}{e_1}\right| \text{ should be constant} \tag{33}$$

Using equations 32 and 30

$$\frac{1 + (\omega CR_b)^2 \frac{R_c}{R_b}}{1 + (\omega CR_b)^2} + 2\frac{R_c}{R_b} \tag{34}$$

should be constant

Using the decibel notation

$$20 \log\left[\frac{1}{\omega CR_b}\left|\frac{e_3}{e_1}\right|\right] = \text{decibel attenuation} - 20 \log \omega CR_b$$

$$= 20 \log\left[\frac{1 + (\omega CR_b)^2 \frac{R_c}{R_b}}{1 + (\omega CR_b)^2} + 2\frac{R_c}{R_b}\right] \tag{35}$$

should be constant

The phase error curves in Figure 17 were obtained by substituting equations 29 and 30 in equation 31.

The attenuation data for the curves in Figure 18 were obtained from the left-hand member of equation 35.

Phase error in degrees is given directly in Figure 17. The magnitude error in decibels is given by the deviation of the curves in Figure 18 from horizontal lines.

In the integrating network used in the

Figure 17. Phase errors in integrating network

Output voltage leads phase of true integration for positive errors and lags for negative

tester, R_c is the effective output impedance of the amplifier stage feeding the network and is therefore fixed, while R_b is adjustable. In actual operation R_b is adjusted to make the phase error zero at the fundamental frequency. The ωCR_c curves (dotted) are shown on Figures 17 and 18 to aid in the analysis of a tester with R_b adjustable and R_c fixed.

Use of the curves will be illustrated by using the constants in the tester described in this paper. Measurements on the V_1 stage showed its effective output resistance to be 24,200 ohms. C is 0.5×10^{-6} farads. So, at the fundamental frequency

$$\omega CR_c = 2\pi 60 \times 0.5 \times 10^{-6} \times 24{,}200 = 4.56$$

Assuming that R_b was originally set too high (R_c/R_b too low), ab (corresponding to $\omega CR_b = 4.56$) is followed downward in Figure 17 until this curve intersects the 0 phase error line. This point, $\omega CR_b = 2.04$, represents the condition of adjustment that gives 0 phase error at 60 cycles per second.

Solving for R_b

$$R_b = \frac{2.04}{\omega C} = \frac{2.04}{2\pi 60 \times 0.5 \times 10^{-6}} \doteq 10{,}830$$

and

$$\frac{R_c}{R_b} = \frac{24{,}200}{10{,}830} = 2.23$$

bc, therefore, gives the phase error in the tester for varying ωCR_b (or varying frequency as C and R_b are now fixed).

If there are no even harmonics in the supply voltage, the first component frequency of importance above the fundamental is the third harmonic. This corresponds to $\omega CR_b = 2.05 \times 3 = 6.12$. At this point bc shows the phase error to be about -0.28 degree. For the higher order harmonics the error becomes gradually less. Note that the phase errors shown are degrees at the particular frequency plotted.

Thus the time error at the third harmonic would be

$$\frac{1}{180} \times \frac{0.28}{360} = -4.32 \times 10^{-6}$$

second rather than three times this value.

With the proper adjustment on R_b, the network will correct for small phase errors in other parts of the B circuit. For instance, the error due to R-C coupling in amplifiers would be corrected by making R_b less than the value giving zero error in the integrator alone, thereby shifting to one of the lower R_c/R_b curves. As the two error curves are of different shapes, the net error will necessarily be zero at the fundamental frequency only. For this reason phase errors in the remainder of the vertical system should be kept as small as possible.

The curve bc in Figure 18 is obtained in a similar manner to bc in Figure 17. A discrepancy of about 0.3 decibel (3.5 per cent) for the third and higher harmonics with respect to the fundamental is shown.

Figure 18. Attenuation in integrating network

Appendix III. Analysis of Calibrating System

The voltage e_p induced in the pickup coil and applied to the input of the preamplifier is

$$e_p = 10^{-8} N_p \frac{d\Phi_f}{dt} \tag{36}$$

where

N_p = number of turns in pickup coil
Φ_f = intrinsic flux in sample
t = time in seconds

But if B_f is the intrinsic induction in the sample

$$\Phi_f = \frac{\pi}{4} \times 2.54^2 \times 10^{-6} a^\pi B_f \tag{37}$$

where a^π is the area of the sample in circular mils and

$$e_p = 10^{-14} \frac{\pi}{4} \times 2.54^2 N_p a^\pi \frac{dB_f}{dt} \tag{38}$$

Neglecting phase and magnitude errors in the preamplifier and integrator, the voltage applied to the cathode-ray oscilloscope input terminals, with switch on "measure" is

$$e_o = K_b \int e_p dt = 10^{-14} \frac{\pi}{4} \times 2.54^2 N_p a^\pi K_b \int dB_f \tag{39}$$

where K_b is an adjustable constant depending on the B gain setting and the characteristics of the preamplifier and integrator.

The vertical deflection of the oscilloscope, again neglecting errors of phase and magnitude in the oscilloscope, is, by integration of equation 39

$$d_v = K_e e_o = 10^{-14} \frac{\pi}{4} \times 2.54^2 N_p a^\pi K_b K_e B_f \tag{40}$$

The constant of integration is necessarily 0 because of the blocking action of coupling capacitors in the amplifiers. K_e depends on the vertical gain setting on the oscilloscope.

Equation 40 shows that the integrator makes the vertical deflection proportional to B_f rather than its time derivative.

With no sample in the tester and with the switch on high calibration the only voltage applied to the input of the preamplifier is that caused by the calibrating mutual inductor, as the induced voltage in the pickup coil is balanced by that of the balancing mutual inductor.

This voltage is

$$e_c = M_c \frac{di_p}{dt} \tag{41}$$

where M_c is the henrys mutual inductance of the calibrating mutual inductor, and i_p is the current in the primary circuit.

Substituting from equation 16 in Appendix I

$$e_c = \frac{M_c}{44.2} \times \frac{dH_{ca}}{dt} \tag{42}$$

where H_{ca} is the magnetizing force in the H coil during the calibration adjustment. The vertical deflection on calibrating is

$$d_{vc} = K_b K_c \int e_c dt$$

$$= \frac{M_c}{44.2} K_b K_c \int dH_{ca}$$

$$= \frac{M_c}{44.2} K_b K_c H_{ca} \tag{43}$$

Equation 43 shows that d_{vc} is proportional to H_{ca} and therefore the trace on the screen should be a straight line during the calibration adjustment. This allows obtaining the proper phase adjustment in the integrator by setting the adjustment so that the trace on the screen is a straight line.

For maximum values in equation 43

$$D_{vc} = \frac{M_c}{44.2} K_b K_c H_{cal} \tag{44}$$

where D_{vc} is the maximum vertical deflection and H_{cal} the maximum magnetizing force. H_{cal} is the value indicated by the H meter as it operates as a peak meter.

It has been stated previously that the calibrating system was to be arranged so that on the high calibrating position

$$H_{cal} = 2a'' B_{cal} \times 10^{-8}$$

Substituting this in equation 44

$$D_{vc} = \frac{M_c}{44.2} K_b K_c 2a'' B_{cal} \times 10^{-8} \tag{45}$$

where B_{cal} is the value of B_i being calibrated. From equation 45 the B_i scale factor is

$$\frac{B_{cal}}{D_{vc}} = \frac{10^8 \times 44.2}{M_c K_b K_c 2a''} \tag{46}$$

Furthermore, this same scale factor is to apply in equation 40 for all values of B_i and d_v so that

$$\frac{B_{cal}}{D_{vc}} = \frac{B_i}{d_v}$$

$$= \frac{4 \times 10^{14}}{\pi \times 2.54^2 N_p a'' K_b K_c}$$

$$= \frac{10^8 \times 44.2}{M_c K_b K_c 2a''} \tag{47}$$

from which

$$M_c = \frac{44.2 \times 10^{-8} \times \pi \times 2.54^2 \times N_p}{4 \times 2} \tag{48}$$

Substituting 16,000, the number of turns in the pickup coil, for N_p

$$M_c = 1.792 \times 10^3 \text{ henry} \tag{49}$$

The calibrating mutual inductor was designed for a somewhat higher value and was then adjusted to this value by removing primary turns and setting the relative position of the two parts of the inductor. The bridge circuit of reference 6, was used in making this adjustment.

When the switch is in the low calibration position, the 100/1 voltage divider is active, and for this position the calibrating formula is

$$H_{cal} = 2a'' B_{cal} \times 10^{-8} \times 10^2$$
$$= 2a'' B_{cal} \times 10^{-6}$$

Discussion

H. J. McCreary (Automatic Electric Company, Chicago, Ill.): In the Automatic Electric Laboratories we have done some work closely related to this paper.

In the study of magnetic devices employing saturation phenomena, it is sometimes desirable to view the wave shape of the flux against time. For several years we used an exploring coil in series with a high resistance connected to a large capacitor to reproduce by electrical integration in electrical wave form the wave form of the flux through the exploring coil. This device became a tool of more general use about the laboratory and therefore was written up and designated *ELS*-2612, *ELS*-2613, and *ELS*-2614 so that others in the laboratory might make more general use of this test method.

Because of the extreme simplicity of this arrangement, and because of the high impedance across the exploring coil output terminals there is very little reaction of the exploring coil on the flux threading it, and its terminal electromotive force varies almost directly as $d\phi/dt$ 10-8.

It is believed that the comments of Doctor Arthur Bessey Smith and myself as given in *ELS*-2612, *ELS*-2613, and *ELS*-2614 are appropriate additional comments on this paper.

Magnetic Flux on Oscilloscope

Consider one transient, the magnetic flux rising from zero to a finite value. In Figure 1 of this discussion let

ϕ = magnetic flux inside the coil of N turns.
R is a nonreactive resistor which is large enough to dominate the circuit.
C is a capacitor large enough to have a reactance which is small compared to R.
E = electromotive force developed in the coil by the rising magnetic flux.
i = instantaneous current resulting from E.
e is the electromotive force across C resulting from current.

Figure 1

Figure 2

The N-turn coil also must have negligible reactance compared to R. Hence, the whole acts like a noninductive circuit, and the current at any instant will be proportional to E, the electromotive force being generated at that instant by the rising flux ϕ.

The logical development of equation 7 is as follows:

$$e = \frac{q}{C} \tag{1}$$

$$q = \int_0^t i dt \tag{2}$$

Put equation 2 into equation 1.

$$e = \frac{1}{C} \int_0^t i dt \tag{3}$$

$$i = \frac{E}{R} \tag{4}$$

Put equation 4 into equation 3.

$$e = \frac{1}{CR} \int_0^t E dt \tag{5}$$

$$E = 10^{-8} N \frac{d\phi}{dt} \tag{6}$$

Put equation 6 into equation 5.

$$e = \frac{10^{-8} N}{CR} \int_0^t d\phi$$

so that

$$e = \frac{10^{-8}N}{CR}\left[\phi\right] \tag{7}$$

Hence the instantaneous electromotive force e across the capacitor is directly proportional to the magnetic flux ϕ existing at the time t. This is valid under the above conditions and for this first single transient.

Magnetic Flux Intensity Waves on the Cathode Ray Oscillograph

In order to get an oscillogram of the magnitude of flux with respect to time it has been customary in the past to cause a part of the magnetic field to pass through the scope tube and deflect the cathode beam directly, in which case

$$F = BLi$$

However, in the development of electromagnetic apparatus such as relays, stepping switches, and so forth, the magnetic field is often of such a restricted order that the above method of obtaining an oscillogram of the flux variation with time is not practical. In such a case the following method has been found quite practical.

Place an exploring coil about the place in the magnetic circuit where it is desirable to obtain the flux variation.

The voltage generated by the exploring coil is

$$e_{exp} = \frac{d\phi}{dt}10^{-8}$$

$$e_{exp}\,dt \times 10^{+8} = d\phi$$

$$\phi = \int d\phi = 10^{8}\int e_{exp}\,dt$$

Therefore, it is but necessary to integrate the potential e_{exp} electrically with respect to time and place the result on the oscilloscope. The most simple circuit for doing this is shown in Figure 2 of the discussion.

It consists of an exploring coil connected in series with a very high resistance such as 20 megohms and a 1-microfarad capacitor. This circuit then has a time constant of 20 seconds or, in other words, is comparable to that of the needle of the Grassot Fluxmeter.

The vertical oscillograph deflection varies directly as the magnitude of the flux traversing the exploring coil.

Caution: While the time constant of the integration circuit given here is 20 seconds, only the very best cathode ray oscillographs can record accurately frequencies as low as a few cycles per second. Therefore, some discretion must be shown in the selection of an oscillograph which will show accurately the potential across the 1-microfarad capacitor.

Electrical Integration

As mentioned, the potential on the exploring coil terminals when connected to a 20-megohm resistor is practically equal to the electromotive force generated in the coil by the flux change through the coil; that is

$$e = \frac{d\phi}{dt}10^{-8}$$

At frequencies of one cycle per second and greater the potential on the capacitor can never be an appreciable part of the applied potential because the time constant is 20 seconds.

At frequencies of ten cycles per second the potential on the capacitor resulting from accumulated charge through the 20-megohm resistor is so small that it has no appreciable affect on the flow of current caused by the exploring coil. The reactance of 1 microfarad on 10 cycles per second is about 159,000 ohms which, compared to 20 megohms, can be neglected because the voltage drop in the capacitor is about one-half of one per cent of the voltage applied to the circuit.

Therefore, we can conclude that within the accuracy of most indicating instruments the flow of current through the 20-megohm resistor is a direct function of the electromotive force generated by the exploring coil and neglecting the capacitor; that is

$$e_{exp} = ir$$

$$e_{exp} = i\,20\times10^{6}$$

$$i = \frac{e_{exp}}{20\times10^{6}}$$

The voltage on the capacitor is

$$e_{CD} = \frac{Q}{C}$$

where Q is the quantity of charge in coulombs, but

$$Q = \int i\,dt$$

$$Q = \frac{1}{20\times10^{6}}\int e_{exp}\,dt$$

$$e_{CD} = \frac{Q}{C}$$

$$= \frac{1}{C}\,\frac{1}{20\times10^{6}}\int e_{exp}\,dt$$

Therefore e_{CD} is the integral curve of e_{exp}.

Although e_{CD} varies as the flux almost exactly, it is as stated before very small; therefore, it must be applied to a very good amplifier to obtain a voltage large enough to give an appreciable deflection of the cathode ray oscillograph beam.

B. M. Smith (General Electric Company, Schenectady, N. Y.): This paper should be of particular interest to anyone who has made similar measurements and experienced any of the measuring difficulties. The authors are to be commended for their excellent accomplishments and their valuable contributions to the art of magnetic measurements.

As the authors have demonstrated, making magnetic hysteresis loop measurements on a cathode ray oscillograph screen is a very convenient method and greatly facilitates the work where a large number of tests are to be made. This method, however, is not limited to alternating current but has been found very useful for making d-c loops.[1]

One of the errors noted by the authors in the tester was described as being caused mainly by the rectifier type voltmeter, the error being as high as 20 per cent. This is contrary to our experience with this type of instrument which we have found to be accurate within one-half of one per cent at 25 degrees centigrade. Compensation for temperature changes sometimes is incorporated in the instrument. That this accuracy can be obtained is indicated by the recommendations of the American Society for Testing Materials in their test procedures given in *A*34 on magnetic test methods.

The selection of the power line frequency by the authors for the measurement described eliminates many of the difficulties and gives results which were comparable with those obtained by d-c measurements. The question arises, however, as to whether the measurement represents the property of the materials at the higher frequencies at which the recorder wire is supposed to respond. Our experience has been that the frequency response curve for magnetic materials is not related directly to the coercive force obtained at 60 cycles. It depends among other things upon the surface resistivity, size of the wire, as well as the magnetic properties.

The cathode ray oscillograph is also very useful in this work for determining the homogeneity of the wire in its final form.

As a comparator the cathode ray oscillograph should yield very satisfactory results when comparing unknown materials with those which have been tested in service, but this comparison should be made over the frequency range at which the wire is to be used; otherwise it may lead to misleading results.

1. A New Photoelectric Hysteresigraph, **R. F. Edgar.** AIEE Transactions, volume 56, 1937, July section, pages 805–9.

D. E. Wiegand: Performance of the simple *R-C* integrator described by H. J. McCreary and B. M. Smith is perfectly satisfactory providing the sample under test is relatively large and the voltage to the integrator, therefore, is of a conveniently large value. However, in the case of small samples such as those for which the tester described in the paper was designed, the pickup coil voltage is sufficiently small as to lend great importance to the voltage loss or attenuation in the integrator. It is mainly for this reason that the integrating network described in the paper was used in preference to the simpler one. The output voltage of this network is about 11 times that of a simple *R-C* integrator providing the same maximum phase error.

The value of the integrating resistor in the simple *R-C* network enters directly into the calibration of the instrument. This is evident from McCreary's equations. We would expect severe difficulties in calibration drift caused by changes from the nominal 20-megohm value of this resistor. Temperature and surface conditions as affected by the atmosphere may have an important effect on the actual resistance of a resistor of this order of size. Of course, these errors can be minimized by wax coating the resistor, paying attention to all insulation in this high impedance circuit, and possibly enclosing the first stage of the amplifier in an atmosphere-controlled chamber.

In order to realize the 20-second time constant, it is necessary that the resistance across

Figure 3

the input of the amplifier, including the leakage resistance of the 1-microfarad capacitor, be high compared to 20 megohms. It may be difficult to obtain a 1-microfarad capacitor having a leakage resistance consistently this high.

A simple *R-C* integrator at the input of the amplifier first was tried in developing our tester. In testing samples at magnetizing forces beyond that required for saturation, it was found that the trace on the oscilloscope screen was wavy at certain parts of the hysteresis loop. It was found that this effect was caused by phase errors resulting from the self-inductance in the pickup circuit. In order to analyze the action of the simple integrating circuit with a series self-inductance, the curves of Figure 3 of the discussion were prepared. In general, the voltage of the pickup coil consists of a fundamental component plus a series of harmonics (usually odd). The voltage relation for any of the frequencies involved is given in equation 1.

$$\frac{V_1}{V_c}=(1-\omega^2LC)+j\omega\sqrt{LC}\,R\sqrt{\frac{C}{L}} \qquad (1)$$

V_1 is the induced (open circuit) voltage in the pickup coil, V_c the voltage across the integrating capacitor, ω the angular velocity corresponding to the frequency of the voltage component, L the total self-inductance in the pickup circuit (henries), C the capacitance of the integrating capacitor (farads), R the total resistance (ohms) in the integrating circuit. In most cases, the integrating resistor is large compared to other resistances in the circuit so that R may be taken as the ohms resistance of the integrating resistor. The curves of Figure 3 are based on equation 1. The tangent of the phase error is the real part of equation 1 divided by the imaginary part.

In the tester as described in the paper, integration is performed after the first stage of the amplifier, and the pickup circuit therefore is loaded only by its own distributed capacitance and by the volume control at the input of amplifier. Even with this arrangement, wavy loops are obtained sometimes when testing samples far beyond saturation. The frequency of these waves was found to be about 14,000 cycles per second. Under these test conditions, apparently, the voltage of the pickup coil has a 233rd harmonic component of sufficient magnitude to excite the pickup circuit at its resonant frequency.

The curves of Figure 3 in this discussion can be used to determine the values of R and C in a simple integrator preceding the first amplifier stage which will perform satisfactorily up to the present limiting frequency of 14,000 cycles per second. The curve for $R\sqrt{\frac{C}{L}}=1{,}000$ shows an error of 0.5 degree at $\omega\sqrt{LC}=0.1$. On this same curve at $\omega\sqrt{LC}=23.3$, 233 times the original value, the error is about 1.3 degrees. The first value corresponds to the fundamental frequency and the second to the 233rd harmonic. Errors within 0.5 degree at the fundamental frequency have been found to produce negligible errors, and the higher phase error at the 233rd harmonic also will have a negligible effect because of the extremely small time-error to which this angular error corresponds.

The self-inductance in the pickup circuit of the tester is about 1.3 henries. Substituting this value for L and 377 for ω in $\omega\sqrt{LC}=0.1$ gives $C=0.054\times10^{-6}$ farad (0.054 microfarad). Similarly, substituting values in $R\sqrt{\frac{C}{L}}=1{,}000$ gives $R=4.9\times10^6$ ohms (approximately 5 megohms).

Placing the integrator ahead of the first stage of the amplifier of course would reduce greatly the problem of amplifier overloading mentioned in the paper. With this location of the integrator, the first amplifier stage would pass the integrated wave (a flat-topped wave) rather than the pip voltage wave of the pickup circuit.

With the integrator at the output of the first stage, however, lower resistances and larger capacitances may be used in the integrating network, and the problem of changes in calibration resulting from surface variations in the resistors is eliminated. With the tester as shown in the paper, providing the gain controls are adjusted properly, samples may be measured well beyond saturation without overloading the amplifier.

With reference to Doctor Smith's comments regarding the 20-per-cent error caused by the rectifier type voltmeter in the tester, in the American Standards for Testing Materials referred to, voltages of the order of 100 volts are measured by the rectifier type voltmeter. In this range of voltage, temperature errors in the rectifier are masked by the relatively large value of series resistance in the voltmeter. In the hysteresis loop tracer, however, it is sometimes necessary to measure values down to a few volts. In this case, the temperature and aging characteristics of the rectifier become much more important, and accurate measurements are difficult. It is believed that the proposed change to a current transformer and ammeter will result in considerably greater over-all accuracy of measurement in the tester.

Doctor Smith infers that it might be desirable to test magnetic recording media at frequencies well up in the audio range rather than at 60 cycles. It is true that the frequency response curve depends on other factors in addition to the basic magnetic properties measured at direct current or a low frequency. If resistivity of the medium in an important factor, it would be desirable to measure this quantity separately and in addition to basic magnetic measurements in a d-c or equivalent tester, rather than making magnetic measurements at a higher frequency, in which case both the resistivity and the basic (d-c) magnetic properties affect the measurements. In general, in studying correlations between basic properties and final performance of a material in order to draw up a specification which will insure satisfactory performance, it is better to measure separately each of the basic factors involved than to measure some quantity which depends on a combination of basic factors.

Shading Coil Calculations for Single-Phase Magnets

C. T. EVANS
FELLOW AIEE

IN a single-phase a-c electromagnet it is customary to provide a shading coil to prevent chatter of the armature against the stationary pole face. Three important affects are produced by the shading coil.

1. At the pole face, the magnetic flux is separated into two parts which are relatively out of phase.

2. The flux density in the "unshaded" area of the pole face is increased.

3. Heating of the magnet is increased because of the watts produced by the current in the shading coil.

Calculation of the watts dissipated in the shading coil and of the instantaneous pull of the magnet are difficult because of the nonlinear relation between the magnetic flux in the steel and the magnetomotive force. It is the purpose of this paper to describe an experimental procedure that has been found useful in the study of this problem, and to offer experimental evidence in support of an approximate method of calculating the shading coil watts.

Theory

Conventional analysis[1] of the shading coil is based on the assumption that saturation of the steel is negligible. In effect it is assumed that the reluctance in the magnetic circuit is constant and is concentrated in the air gap between the pole faces. Experience shows that even with no intentional air gap and with well fitting pole faces there is a reluctance across these surfaces equivalent to that of an air gap approximately 0.001 inch long. Under this assumption, and with sinusoidal flux generated by the exciting coil of the magnet, each of the fluxes and the shading coil current are evidently sine functions.

Figure 1 is a diagrammatic sketch of a single-turn shading coil surrounding approximately two-thirds of the pole face area. The coil passes through a slot dividing the pole faces into the "shaded" area S_2 surrounded by the coil and the unshaded area S_1. Figure 2 is a vector diagram of the magnetomotive forces and of the fluxes across these areas where θ is the phase angle between the fluxes ϕ_1 and ϕ_2, G_2 is the conductivity of the shading coil, ω is the angular frequency, and the total flux ϕ is the vector sum of ϕ_1 and ϕ_2. If $\mathcal{R}_1$ and $\mathcal{R}_2$ represent the reluctances of the two pole areas, and B_1 and B_2 the flux densities, Figure 2 gives

$$\tan\theta = \omega G_2/\mathcal{R}_2 \tag{1}$$

$$\cos\theta = \mathcal{R}_2\phi_2/\mathcal{R}_1\phi_1 \tag{2}$$

$$\phi^2 = \phi_1^2 + \phi_2^2 + 2\phi_1\phi_2\cos\theta \tag{3}$$

Substituting $T = \mathcal{R}_1/\mathcal{R}_2 = S_2/S_1$ in equation 2 and then in equation 3

$$\phi_1^2 = \frac{(1+\tan^2\theta)\phi^2}{(T+1)^2+\tan^2\theta} \tag{4}$$

$$\phi_2^2 = \frac{T^2\phi^2}{(T+1)^2+\tan^2\theta} \tag{5}$$

Watts in the shading coil are evidently

$$P_s = \omega^2 G_2 \phi_{2m}^2/2 \tag{6}$$

If the maximum (peak) flux density in the steel with the shading coil removed ($G_2 = 0$) is represented by B_m, simple substitution and rearrangement of equations 4 to 6 show that the maximum flux density with the shading coil is

$$B_{1m} = B_o B_m$$

Paper 47-17, recommended by the AIEE committee on industrial control devices for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 1, 1946; made available for printing November 18, 1946.

C. T. EVANS is consulting engineer, Cutler-Hammer, Inc., Milwaukee, Wis.

and the shading coil watts per square inch of total pole area S are

$$P_s/S = P_o(\omega l_a B_m^2)$$

where

$$B_o^2 = [(1+\tan^2\theta)(T+1)^2] + [(T+1)^2+\tan^2\theta]$$

$B_o = B_{1m}/B_m$ shows the variation of B_{1m} with constant density B_m

and

$$P_o = [T(T+1)\tan\theta]/2\mu[(T+1)^2+\tan^2\theta]$$

P_o = watts per square inch with unit air gap, flux density, and angular frequency

μ = The permeability of air, and l_a the length of the air gap

Thus B_o and P_o depend only on the ratio of pole reluctances (or areas) T and the phase angle θ. The parameters B_o and P_o are plotted in Figures 3 and 4 as functions of θ, and for several values of T. Watts per square inch total pole area reach maximum values at specific phase angles, depending on T, while the flux densities increase with the phase angle.

On the basis of these simplified assumptions it is usual practice to design a magnet for a phase angle between 60 and 70 degrees and a ratio T in the neighborhood of two. Under these conditions reference to Figure 3 shows that the flux density in the unshaded pole area is from 1.66 to 2.15 times the density in the core, as a whole. Thus, if the maximum density B_m is 0.001 weber per square inch, the maximum density B_{1m} indicated for the unshaded area is from 0.00166 to 0.00215 weber (166 to 215 kilomaxwells) per square inch, or from 30 to 70 per cent above the saturation value in the grade of steel ordinarily used for such magnets. From these considerations it is clear that the reluctance of the steel cannot be ignored, nor can it be assumed that the reluctance is constant.

Approximate Solution

Now in dealing with high flux densities, frequent use is made of published data giving the volt-amperes "excitation" per pound of metal for the steel.

Curves giving these volt-amperes as a function of the maximum flux density, and at 60 cycles, are available for the various standard grades of steel. They presuppose sinusoidal flux variations and (tacitly) nonsinusoidal magnetizing forces. The volt-amperes therefore are the product of the rms values of the magnetizing current and induced voltage in a magnetizing coil which would produce the given sinusoidal flux density in a pound of steel.

It would be attractive to work out an approximation for the shading coil watts based on the known values of excitation P_x for the steel, and also based on a vector representation of the fluxes and current as shown in Figure 2. In effect this means that some equivalent fixed reluctance must be substituted for the variable reluctance of the steel, but that the value of this fixed reluctance varies with the maximum flux density. In order to determine the value of this equivalent reluctance it would be convenient to convert the values of volt amperes excitation to rms ampere turns per inch-cube per weber for the steel. A further convenience results if the ampere turns per inch for the steel plus a small per-unit length of air gap is used. For this purpose assume K inches of air gap for each inch of steel.

$\mu = 3.19 \times 10^{-8}$ for air
γ = pounds per cubic inch of steel
σ = stacking factor of the laminations
P_x = volt-amperes per pound of steel
B_m = webers per square inch
$\mathfrak{R}_o = (2\gamma\sigma P_x)/(\omega B_m^2)$ ampere turns per weber per inch-cube of steel
$\mathfrak{R}_o'$ = ampere turns per weber for an inch-cube of steel plus K inches air gap

$\mathfrak{R}_o' = \mathfrak{R}_o + 10^8 K/3.19$

Figure 1. Single-turn shading coil

Figure 2. Vector diagram of magnetomotive force and flux

Figure 3. Variation of flux density in unshaded pole area

Figure 4. Variation of watts per square inch of pole area

The curves of Figure 5 show $\mathfrak{R}_o' B_m$ as a function of B_m for electrical sheet steel. Now return to the vector relations of Figure 2 and equation 3, noting that

$$\mathfrak{R}_2\phi_{2m} = l\mathfrak{R}_2' B_{2m}$$

with a similar relation for $\mathfrak{R}_1\phi_{1m}$

$$(\mathfrak{R}_1' B_{1m})^2 = (\mathfrak{R}_2' B_{2m})^2 + (\omega S_2 B_{2m} G_2/l)^2 \quad (7)$$

$$\phi^2 = \phi_1^2 + \phi_2^2 + 2\phi_1\phi_2\mathfrak{R}_2' B_{2m}/\mathfrak{R}_1' B_{1m} \quad (8)$$

the conductivity G_2 theoretically should include a term attributable to the watts-per-pound loss in the iron P_r thus

$$G_2 = G_s + (2\gamma\sigma l P_r)/(\omega^2 S_2 B_{2m}^2) \quad (9)$$

where G_s is the conductivity of the shading coil.

However, the last term usually is small compared to G_s, the conductivity of the shading coil, and may as well be omitted considering the degree of approximation involved, so that G_s may be substituted for G_2 in equation 7 without appreciable error. Likewise the iron loss in the unshaded portion can be disregarded.

In practice, the dimensions of the poles, conductivity of the shading coil, and maximum total flux usually are given. To find the watts in the shading coil, proceed by assuming a trial value for B_{2m} and by the curves in Figure 5 find $\mathfrak{R}_2^1 B_{2m}$. Calculate $\mathfrak{R}_1' B_{1m}$ by equation 7 and again by reference to Figure 5, find B_{1m}. Now, multiplying B_{1m} and B_{2m} by the areas S_1 and S_2 of the respective pole sections, find ϕ_{1m} and ϕ_{2m}, and then from equation 8 calculate ϕ_m. If this differs from the actual value of ϕ_m, adjust the trial value of B_{2m} until there is agreement in ϕ_m. The shading coil watts then are

$$P_s = \omega^2\phi_{2m}^2 G_2/2 \quad (10)$$

Measurements made on several commercial magnets of the difference between the watts input with the shading coil in place, and with it removed, gave values for the additional watts attributable to the shading coil agreeing closely with the calculations just outlined. However, it was considered desirable to undertake a more comprehensive study of such magnets, to include effects resulting from variations in physical proportions of the magnet, and to measure the instantaneous flux densities at the pole faces, especially the maximum densities. Although not the subject of the present paper, it may be mentioned in passing that measurement of the instantaneous values of the flux densities have also been used for a general study of the instantaneous magnitudes of the pull developed at the pole faces. The experimental procedure finally adopted permits measurement not only of the instantaneous values, but also of the rms values, as well as direct measurement of the watts over a wide range of physical proportions.

Experimental Procedure

Preliminary tests were made on a large experimental magnet slotted at the pole

Figure 5. Ampere turns per inch for steel with air gap

Figure 6. Voltages and fluxes for magnet, Figure 1

Figure 8. Voltages and fluxes for rings, Figure 7

face to receive a shading coil as well as additional fine wire search coils, by means of which the instantaneous voltages induced by the fluxes in both sections were indicated on an oscilloscope and recorded photographically. Figure 6 shows a trace of the volts per turn in the search coils, as well as the magnetic fluxes obtained by graphical integration of the flux curves. The pertinent data are:

$S_2 = 3$ square inches
$S_1 = 1.37$ square inches
$l = 7/16$ inch
$G_2 = 111$ mhos

The low resistance exciting coil had 245 turns and, for these curves, was energized at 300 volts, 60 cycles.

The technical difficulties attendant on the use of the oscilloscope were such as to suggest a modified arrangement wherein the voltages could be recorded by an oscillograph, particularly as it was desired to obtain a large number of curve traces. Furthermore, with this magnet the effective air gap at the pole faces could not be reduced below approximately 0.001 inch, and could not be controlled easily for larger values.

It was decided to set up an equivalent electromagnetic circuit consisting of two separate laminated steel rings, having separate identical exciting coils connected in series across the a-c source. These two rings represent the unshaded and shaded pole sections, and a resistance shunt, connected across the exciting coil of the "shaded" ring, represents the shading coil. Figure 7 is a diagram of the arrangement. The rings were made by winding electrical strip steel on arbors, with 0.001-inch paper separators between the laminations. Steel rivets were placed around the rings on the center line of the strips to hold them in place and the rings were finally sawed across their diameters. The resulting pole faces were then finished in line, coils inserted, and the rings reassembled with flat insulating plates interposed to control the length of the air gaps. For each ring there are two low-resistance coils of 122 turns each, or 244 turns for the ring. The mean length of the strips for each ring is 32.7 inches and the cross-sectional areas of the unshaded and shaded rings are 1.5 and 3.0 square inches respectively.

A little consideration will show that the differential equation connecting the magnetic fluxes and magnetomotive forces for these rings is of the same form as for the individual sections of the magnet of Figure 1. The resistance of the exciting coils may be neglected if low-resistance coils are used. For the magnet of Figure 1, as the magnetomotive force, integrated over a path from a point in the upper pole to a point in the lower pole is the same, whether the path of integration passes through or outside of the shading coil

$$\mathfrak{R}_1\phi_1 = \mathfrak{R}_2\phi_2 + G_2\frac{d\phi_2}{dt} \tag{11}$$

Figure 7. Connections for test of steel rings

For the two rings, moreover, the instantaneous currents

$$i_1 = i_2 + i_s \tag{12}$$

But we have

$$\left.\begin{aligned} Ni_1 &= \mathfrak{R}_1\phi_1 \\ Ni_2 &= \mathfrak{R}_2\phi_2 \\ i_s &= NG_2'\frac{d\phi_2}{dt} \end{aligned}\right\} \tag{13}$$

Substituting equation 13 in 12 gives

$$\mathfrak{R}_1\phi_1 = \mathfrak{R}_2\phi_2 + N^2G_2'\frac{d\phi_2}{dt} \tag{14}$$

In these equations R_1 and R_2 need not be constants, so that the equivalence between the single magnet and the rings of Figure 7 hold regardless of this condition, provided that in each case the $\mathfrak{R}$'s are similar functions of the ϕ's. Thus, if the conductance of the shunt circuit around the exciting coil of ring 2 is multiplied by N^2 and the current in this circuit is multiplied by N, the results are respectively the conductivity and current in an equivalent single-turn shading coil around the shaded pole section, now represented by ring 2. These two rings therefore truly represent the shaded and unshaded pole sections of a magnet, each having an iron path 32.7 inches long, and adjustable air gaps which may be made very short compared to the length of the iron path.

Incidentally, in setting up the rings with an equivalent air gap of K inches per inch length, each of the two gaps in a ring should have a length somewhat longer than $lK/2$ as the effect of fringing may be appreciable with these longer air gaps. The permeance of the fringing path may be calculated by any standard method[1] and the actual air gaps should

be increased by an amount proportional to the per-unit permeance of the fringing path. This increase may amount to 0.2 of the equivalent air gap.

Several advantages accrue from the use of these rings, among which are:

(*a*). There is no unused iron in the rings compared to the return magnetic circuit of Figure 1.

(*b*). The air-gap length may be adjusted so as to study the effect of varying K.

(*c*). With low-resistance exciting coils, the terminal voltages may be assumed to be equal to the induced voltages, and may be recorded on an oscillograph, or the rms values may be measured directly without further amplification.

As an example, Figure 8 shows a trace of an oscillogram of the voltages recorded while testing these rings, with 326 volts, 60 cycles, impressed and with 20.1-ohm shunt around coil 2. The reluctance of the air gaps in ring 1 is 1.16×10^6 ampere turns per weber, and for the (shunted) ring 2, 0.542×10^6 ampere turns per weber. The corresponding values of K are 0.0021 and 0.0017 respectively. By voltmeter measurement there are 224 volts across coil 2, giving 2,490 watts dissipated in the 20.1-ohm shunt.

If the assumption were made that all of the reluctance is concentrated in the air gap, equation 2 would give the phase angle

$$\theta = \tan^{-1}(\omega G_2/\mathfrak{R}_2) = 64 \text{ degrees}$$

Therefore

$$T = 1.16/0.52 = 2.14$$

$$\tan\theta = 2.06$$

The total flux for the two rings

$$\phi_m = 326\sqrt{2}/(244\omega) = 0.00502 \text{ weber}$$

by equation 5

$$\phi_{2m} = \frac{2.14\times0.00502}{[(3.14)^2+(2.06)^2]^{1/2}} = 0.00287 \text{ weber}$$

The rms volts across coil 2 would then be $\omega N\phi_{2m}/\sqrt{2}$, or 186.5 volts, which would produce only 1,650 watts in the 20.1-ohm shunt. This is 23 per cent low compared with the 2,490 watts actually measured.

By making use of the approximations of equations 7, 8, and 9, with a trial value for B_{2m} of 0.00114 weber per square inch, and by reference to Figure 5, with K at 0.0017, $\mathfrak{R}_2'B_{2m}$ is found to be 215. Then with 2,960 mhos for G_2, equation 7 gives 245 for $\mathfrak{R}_1'B_{1m}$. Reference to Figure 5, using 0.0021 for K, then gives 0.0015 for B_{1m}. The corresponding fluxes are

$$\phi_{1m} = 0.00172 \text{ weber}$$

$$\phi_{2m} = 0.00342 \text{ weber}$$

and, using equation 8,

$$\phi_m = 0.005 \text{ weber}$$

This compares with the actual value 0.00502 weber. For a single-turn shading coil having a conductivity, 2,960 mhos, the watts

$$P_s = (120\pi\, 0.00342)^2\, 2{,}960/2 = 2{,}460 \text{ watts}$$

compared with the test value, 2,490 watts. A number of similar calculations and tests give results, comparable within 10 per cent or less in all cases.

With a pair of laminated steel rings, having an appropriate ratio of cross-sectional areas, it is possible to measure the rms volts or current in the shunt circuit by means of ordinary a-c voltmeters or ammeters and thus quickly determine the shading coil watts for any equivalent magnet over a wide range of shading coil conductivities, air-gap ratios, and exciting voltages or frequencies without having to build and test the actual magnet. Other studies, covering a similar range of variations, concerning flux densities or instantaneous pulls readily will suggest themselves.

Conclusion

A procedure has been suggested by means of which the watt loss in the shading coil of a single-phase magnet may be calculated with reasonable accuracy. An experimental method has been described by means of which the validity of these approximate calculations has been confirmed. This experimental method also may be used effectively to study the nonlinear relationships between the magnetic fluxes and magnetomotive forces in single-phase shaded-pole magnets over a wide range of physical proportions.

Appendix. Nomenclature

B_m	= peak flux density for magnet pole as a whole, or when shading coil is removed
B_{1m}, B_{2m}	= peak flux densities, unshaded and shaded poles respectively
B_o	= ratio B_{1m}/B_m
G_s	= conductance of single turn shading coil
G_2	= equivalent conductance of shading coil plus that of the steel in the shaded pole
G_2'	= conductance of the shunt around the coil of ring 2
K	= ratio l_a/l
l	= length of pole (see Figure 1)
l_a	= length of air gap (see Figure 1)
P_s	= watts dissipated in hading coil
P_o	= watts per square inch of total pole area with unit air gap, flux density, and angular frequency
P_r	= watts per pound of steel
P_x	= volt-amperes excitation per pound of steel
$\mathfrak{R}_1$, $\mathfrak{R}_2$	= reluctances of unshaded and shaded poles
$\mathfrak{R}_1'$, $\mathfrak{R}_2'$	= equivalent reluctance of an inch-cube of steel plus K inches of air gap, for the unshaded and shaded poles
$\mathfrak{R}_o$	= equivalent reluctance of an inch-cube of steel, for a given peak flux density
$\mathfrak{R}_o'$	= equivalent reluctance of an inch-cube of steel plus K inches of air gap
S	= combined area of shaded and unshaded poles
S_1, S_2	= areas of unshaded and shaded poles
T	= ratio $S_2/S_1 = \mathfrak{R}_1/\mathfrak{R}_2$
γ	= pounds per cubic inch of steel
θ	= phase angle between ϕ_1 and ϕ_2
μ	= permeability of air
σ	= stacking factor
ϕ, ϕ_1, ϕ_2	= total flux, unshaded and shaded pole flux
ϕ_m, ϕ_{1m}, ϕ_{2m}	= peak values of fluxes

Discussion

J. E. Ryan (General Electric Company, Schenectady, N. Y.): The conventional method of analyzing shading coil action, neglecting the reluctance of the iron in the vicinity of the butting surfaces, is useful only for visualizing the general effects of the parameters involved. For design, methods akin to C. T. Evans' "approximate solution" have had to be employed, and even then the prediction of maximum quiet pull is not as accurate as that for the shader losses.

The real contribution of this paper is the ingenious equivalent circuit of Figure 7. Working with controllable air gaps and easily measurable quantities, data can be obtained which, when plotted in dimensionless form, will be directly usable in design It should be noted, however, that the equivalent circuit represents none of the iron beyond the depth of the shader slot. Tacitly it is assumed that the flux density is uniform across the section beyond this point. Even if one attempts to allow for the approaches to the shaded and unshaded regions by adding some equivalent length of iron, this is not strictly accurate as the

latter varies cyclically with time. But such refinements are unnecessary because the air gap in an actual magnet is rather indeterminate anyway.

The writer feels that the paper would have been easier to follow if a complete notation had been given at one place, including some subscripts and superscripts not explicitly defined. Also, an appendix containing the complete proof of the similarity of the actual magnet and the equivalent circuit would have been helpful.

There seem to be two errors in the paragraph following equation 14. By independent analysis, the writer has found that

$$G_2 = N^2\left(\frac{S_2'}{S_2}\right)\left(\frac{l_a}{l_a'}\right)G_2'$$

instead of

$$G_2 = N_2 G_2'$$

and that

$$i_s = N\left(\frac{l_2}{l_a'}\right)i_s'$$

instead of

$$i_s = N i_s'$$

where the notation is that of the paper, and primes denote properties of the model.

A further interesting consequence is that

$$P_s = \left(\frac{l_a S_2}{l_a' S_2'}\right)P_s'$$

It is hoped that the author subsequently will present data on the relations between pull, heating, and the various design parameters.

L. A. Doggett (Pennsylvania State College, State College, Pa.): The literature on shading coil design is not very extensive. A brief bibliography of this subject is given on page 22 of bulletin number 52 of the Pennsylvania State College Engineering Experiment Station, entitled "Design of Shading Coils for A. C. Electromagnets." To this list should be added the work of H. C. Roters and now the present paper by C. T. Evans.

In Evans' paper an equivalent electromagnetic circuit has been devised in which the important variables are dualed in a very ingenious manner. The actual magnetic circuit corresponding to Figure 1 consists of two branches in parallel carrying fluxes ϕ_1 and ϕ_2, which in combination yield ϕ. The ϕ_1 branch contains a reluctance $\mathfrak{R}_1$ properly modified to include some iron reluctance. The ϕ_2 branch contains a reluctance $\mathfrak{R}_2$ plus an opposing magnetomotive force caused by the shading coil. Various equivalent circuits have been proposed, notably by Unger, and now by Evans in Figure 7. Figures 6 and 8 substantiate the author's claim as to equivalence. A further equivalence might well be pointed out. If in Figure 8, e_2 and e_1 are added, a very good sine wave of impressed electromotive force is obtained. In Figure 6, where

$$\phi_1 + \phi_2 = \phi$$

$$n\frac{d\phi_1}{dt} + n\frac{d\phi_2}{dt} = n\frac{d\phi}{dt}$$

$$n = 1$$

e_2 plus e_1 also add up to a good sine wave.

Granting that Figure 7 is a satisfactory equivalent, it might be suggested that its use be extended to find out the optimum values of shading coil resistance S_2/S_1 and air gap length for the unshaded part. By optimum values are meant those values which produce a minimum of vibration. To carry out these tests it would be necessary to fasten the lower semicircular cores securely to the laboratory table, whereas the upper semicircular cores should be fastened firmly together but otherwise be free to move. A crystal-type vibration pickup and a cathode-ray oscilloscope may be used to observe the vibration of the upper pair of semicircular cores. The weakness of all analytical methods so far presented lies in their failure to consider the presence of harmonics in the shading coil current. The driving electromotive force of this current, e_2, is far from sinusoidal. However, Evans' experimental arrangement of Figure 7 will have voltage and current wave shapes very similar to those existing in ordinary shading coils.

Finally for the benefit of those investigating this subject for the first time a brief statement of the elementary theory is presented. Using the notation of the present paper, a Kirchhoff's law equation may be set up for the magnetic circuit of Figure 1 Thus

$$-\phi_2\mathfrak{R}_2 - 0.4\pi N_2 i_s + \phi_1\mathfrak{R}_1 = 0$$

If $\phi_1 = \phi_2 \sin \omega t$, then

$$-(\mathfrak{R}_2\phi_2 \sin \omega t - 0.4\pi N_2 G_2(-N_2\omega\phi_2 10^{-8}) \times \cos \omega t + \mathfrak{R}_1\phi_1 \sin (\omega t - \theta) = 0$$

For $\omega t = 0$ and $\omega t = \pi/2$, two important relationships may be derived.

$$\sin \theta = \frac{0.4\pi N_2\omega N_2}{\mathfrak{R}_1 10^8} G_2 \frac{\phi_2}{\phi_1} \qquad (1)$$

$$\cos \theta = \frac{\mathfrak{R}_2\phi_2}{\mathfrak{R}_1\phi_1} \qquad (2)$$

Equation 2 is the same as that in the paper. Equation 1 of the paper may be obtained by the relationship $\tan \theta = \sin \theta / \cos \theta$.

C. T. Evans: As stated in the paragraph following equation 14, the differential equations 11 to 14 are sufficient to prove the equivalence between the ring model and an actual magnet having the same pole dimensions. If one wishes to build a ring model equivalent to any specific magnet, the complete equivalence requires that B_m, ω, K, and T have the same values in the model as for the magnet. Then the following relations hold, where primes refer to the model.

$$P_s'/l'S' = P_s/lS$$
$$G_s' N'^{2} S'/l' = G_s S/l$$

Subscripts for S and l are unnecessary in view of the required invariance of K and T.

Several people have referred to the desirability of developing a criterion for an "optimum" design of a shaded pole. This optimum design would no doubt be such that, given B_m, l, and K, and curves for the reluctivity of the steel, definite values for T and G_s could be derived such that either (*a*) the ratio (minimum instantaneous force)/(watts in shading coil) is a maximum, or (*b*) for a given required minimum instantaneous force per square inch of pole area, the resulting watts in the shading coil per square inch of pole area is minimum. Criterions (*a*) and (*b*) are not necessarily the same. For reasons stated in the paper, ring models would be very helpful in any general investigation of this kind.

A Thrustor Lowering Control System for A-C Crane Hoists

E. L. SCHWARZ-KAST
ASSOCIATE AIEE

THE common interest in a-c lowering controls for crane hoists has increased steadily in the last few years. This trend is very natural because the present power plants are generating a-c power almost universally and conversion into direct voltage is costly and inconvenient.

The General Problem of Lowering Control

For those who do not work every day in this field and are probably not so aware of the problem involved, a brief description of the situation should be given. The problems of speed control for crane hoists are more involved than those for general drives. For speed control of electric drives in general we have to consider load changes ranging from zero to full load. In the case of a crane hoist, the motor load might change from zero to full load during hoisting and from +10 per cent for lowering the empty hook to −64 per cent for lowering the full load.

Another difference between general drives and hoist drives is the fact that in the case of general speed control, failure of the control merely would stop the operation, but usually nothing more would happen. In the case of a crane hoist, failure of the control might cause the abrupt dropping of the load, an extremely dangerous situation. Consequently, in the case of crane hoists the utmost safety in operation is imperative, preceding all other requirements.

Paper 47-19, recommended by the AIEE committee on industrial control devices for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 12, 1946; made available for printing December 16, 1946.

E. L. SCHWARZ-KAST is a research electrical engineer with the Armour Research Foundation of Illinois Institute of Technology, Chicago, Ill.

The requirements of a satisfactory hoist control are shown in Figure 1 and are as follows:

1. Safety in operation. Ruggedness and simplicity of apparatus are essential.
2. To hoist all normal loads at slow, medium and high speed.
3. To lower all loads at a slow, medium and high speed.
4. To provide accurate positioning of all loads, overhauling or non-overhauling (so-called inching).
5. To avoid too high currents to reduce heating of motors and apparatus.

With the passing of time the problem of speed control for lowering loads is becoming increasingly difficult. For example, for machine shop cranes the modern machine tools and methods of machining require a greater accuracy of positioning and, on the other hand, there is a general trend toward increase of the full speed for speeding up production to the highest possible degree. The result is that the range of speed control required is increasing steadily.

The Present A-C Lowering Systems for Crane Hoists

The various systems which are at present in use for a-c lowering and which are known most commonly are

1. Oversynchronous lowering with squirrel cage and wound-rotor motors.
2. Multispeed motors, squirrel cage, wound-rotor or combined wound-rotor, squirrel-cage motors.
3. Mechanical load brake, wound-rotor motor and rotor resistors.
4. A-c commutator motor with shunt characteristic and brush shifting.
5. Dynamic braking with wound-rotor or squirrel cage motors and direct voltage applied to the stator windings.
6. Counter-torque (plugging) with wound-rotor motor in combination with oversynchronous lowering.
7. Wound-rotor motor, rotor resistances, and unbalanced voltage, using an autotransformer with multiple taps in one phase.
8. Variable unbalanced voltage. The unbalance is obtained by a saturable reactor in one motor lead. This reactor is saturated automatically in proportion to the motor speed. The rotor voltage is used as a simple and reliable speed indicating means which varies inversely proportional to the speed. The rotor voltage furnishes, through an amplifier, a d-c output inversely proportional to the speed which is used in the reactor for obtaining the necessary unbalance of the primary voltage.
9. Motor-generator set, d-c hoist motor, and variable voltage control. (Ward-Leonard system)

Table I shows the main properties of the various systems and the approximate initial cost of the electrical hoist equipment as compared with the cost of item 1, oversynchronous lowering, which is the lowest and is assumed as 100 per cent. Also, the last column of the table shows the inconvenient features of the various systems. This table shows very clearly that there is a definite demand for an a-c lowering system which is simple, safe, has low current consumption, assures reasonable speed reduction and easy inching, and is inexpensive. It is believed that

Figure 1. The ideal speed-load diagram for a crane hoist

Table I. Comparison of Common Systems of A-C Lowering

Item	A-C Lowering System	Creeping Speed 64% Negative Load % Full Speed	Current Consumption	Approx. Initial Cost	Safety in Operation	Inching	Notes
1	Oversynchronous lowering	Approx. 105%	Low	100%	Good	Fair	No speed reduction below 105% except by inching.
2	Multi-speed motor	Approx. 25%	Low	150%	Good	Good	Squirrel-cage motor characteristics. Abrupt acceleration no gradual speed increase.
3	Mechanical load brake	Approx. 25%	About 50% of rating	130%	Good	Fair	Assumed best adjustment of the load brake. Continuous wear requires permanent care and adjustment.
4	A-C commutator motor	Approx. 25%	Low	150%	Good	Good	Unconventional, custom-built motor type, maintenance of commutator and brushes, but extremely simple control by brush shifting.
5	Dynamic braking with direct voltage	Approx. 25%	Low	130–150%	Fair	Fair	For overhauling loads only. The necessary rectifier is an additional device, and as such it decreases safety in operation.
6	Counter torque	Approx. 10%	Low	125%	Good	Handicap	Light loads might be lifted. Recommended for predetermined loads.
7	Adjustable unbalance voltage	Approx. 40%	High, up to 230% of rating	130%	Good	Good	The speed reduction at full load is limited. A convenient reduction only obtainable for loads smaller than 60% of full load.
8	Variable unbalance voltage	Approx. 20% with all loads and 30% for light hoist	Line current at lowering can be limited to 125% rated	180%	Fair	Better than number 7	An ingenious system. The characteristics are satisfactory, but the addition of quite a number of apparatus capacitors, transformers, and rectifiers is not very desirable.
9	Ward-Leonard	Approx. 10% with all loads, best speed adjustment, and smooth acceleration	Over-all efficiency is low.	250%	Best	Best	Weight and space requirements of the motor-generator set. Care for commutator and brushes. Standby consumption of motor-generator set is inconvenient.

the Thrustor lowering system which will be described next has these properties to a high degree. The principles of the Thrustor Lowering control are protected to the General Electric Company, and this system has been in use since 1941.

The Thrustor Lowering System

As commonly known, wide range speed reduction can be obtained with a wound-rotor motor and resistors in the rotor circuit, provided the motor is loaded substantially and an appreciable current is flowing through the resistors. Furthermore, it is also commonly known that every crane hoist is equipped with a stop-brake for holding the load at rest at any level. This stop-brake conventionally consists of a brake drum and lined brake shoes, which are pressed by a compression spring on the drum to develop the necessary brake torque. The brake is released electrically by an electromagnetic device such as a solenoid, a torque motor, or a Thrustor. Thrustor is the trade name of an electrohydraulic device developed by the General Electric Company for activating servomechanisms of any kind and especially for brake release.

Figure 2 shows an exploded view of a Thrustor. This device consists of a cylinder in which a piston is traveling. The cylinder below the piston is filled with oil, and a motor driven impeller provides oil pressure in the cylinder to raise the plunger, thus activating the brake release. An adjustment sleeve valve is inserted in the liquid circuit for providing a time delay of the up or down stroke, whenever desired. The impeller motor is a conventional 4-pole 3-phase squirrel-cage induction motor. If the motor is connected to the line, the piston rises and releases the brake; if the motor is disconnected or the power supply should fail, the motor stops, the up-force at the plunger ceases, the piston returns by its own weight supported by the brake spring in its original position, and the brake is applied. Figure 3 shows a Thrustor-operated stop-brake.

In order to understand the operating principles of the Thrustor lowering system, one more fact has to be borne in mind. The Thrustor develops its rated thrust at full speed of the impeller motor. This is the case when the impeller motor is supplied with 3-phase alternating current of rated frequency and voltage. If this motor is supplied with a lower frequency and proportional lower voltage, its speed decreases practically with the frequency. Consequently, the liquid pressure developed by the impeller decreases approximately as the square of the speed and in turn, the thrust operating on the brake lever is reduced very rapidly with the speed. After knowing these facts the operating principle of the Thrustor lowering system can be understood readily.

This system uses a wound-rotor hoist motor for drive and uses the Thrustor-operated stop-brake for development of the temporary motor load which is necessary for the speed reductions desired. This is accomplished in the following way: The control device, drum-controller or magnetic control, connects the hoist motor to the line in the lowering direction and on the first lowering point a higher ohmic resistor is inserted in the rotor circuit to obtain reduced motor torque (about 1/4 of rated torque) and the Thrustor is not connected in parallel with the stator of the motor as usual, but across the rotor of the hoist motor. Rotor voltage and frequency are speed responsive. At synchronous speed both are zero, and at standstill both have the full rated value. Between synchronous speed and zero speed, rotor voltage and frequency vary inversely proportional to the speed.

Figure 4 shows the thrust on the Thrustor *TF*, the force on the brake shoes caused by the brake spring *BF*, and finally, the force available for brake release *BF-TF* in relation to the speed of the hoist motor. In the range *CD* where the thrust of the Thrustor exceeds the force of the brake spring, the brake is released entirely. This is the case as shown in Figure 4, from standstill up to about seven per cent of full speed. With rising speed the force on the brake shoes *BF-TF* increases gradually with the speed. At about 60-per-cent lowering speed the full force is applied on the brake shoes. At actual lowering, on the first lowering point the motor speed increases,

driven by the lowering load, until the brake torque equals the torque developed by the load plus the torque developed by the hoist motor and an equilibrium is established.

Figure 4 shows that relatively small changes of the motor speed cause a very powerful increase of the brake force *BF-TF*. Consequently, the self-adjusting creeping speed is fairly independent of the magnitude of the load.

A similar Thrustor control readily can be provided also at the first hoisting point. The secondary resistor at this point is laid out for starting the full load safely. Figure 5 shows how these self-adjusted creeping speeds on the first hoisting and the first lowering point change with the load from zero to full load. The creeping speed at hoisting changes from 25 per cent at empty hook to 10 per cent at full load, and the creeping lowering speed from 10 per cent at empty hook to 25 per cent at full load. In general this relatively small change in creeping speed is not objectionable even for cranes where a low creeping speed is imperative, as foundry or machine-shop cranes, and there might be only very few special cases where a more constant speed is absolutely necessary.

A very convenient feature of this Thrustor lowering control is that all loads, from empty hook to full load, start positively with the creeping speed on the first point in either direction, lowering and hoisting as well. This makes the so-important inching particularly simple and reliable.

The Electrical Equipment of Thrustor Lowering Control

Figure 6 shows a wiring diagram for an a-c hoist with Thrustor lowering control. All details are conventional parts, with no special custom-built apparatus necessary. The hoist motor is a standard wound-rotor, crane-duty motor. The ohmic values of the secondary resistors are comparable to the conventional resistors, increased in order to provide the small motor torque required at the first lowering position to keep the burden on the Thrustor lowering brake as low as possible. Regular resistors for 150-per-cent starting torque have approximately $0.38E/I$ ohms per phase: in the case of Thrustor lowering at least $0.5E/I$ ohms is recommended and a further reduction of the motor torque by opening one rotor lead. E is the rotor voltage between slip rings at standstill: I the rotor current per slip ring at full load.

The diagram provides for lowering only three steps, which is sufficient for satisfactory crane operation. At the first lowering point the Thrustor brake, connected to the rotor of the hoist motor, acts as a speed responsive automatic brake, and a high ohmic resistor is inserved in the rotor circuit. All loads start at this point, lowering with creeping speed 10 to 20 per cent of full speed. At the second lowering point the Thrustor brake remains rotor connected, but the rotor resistor is lessened; thus motor torque in the downward direction and lowering speed increase with all loads to 50 to 60 per cent. At the third point the Thrustor, now connected to the line, acts like a regular stop-brake; the rotor resistor is short circuited and the motor operates as an asynchronous generator, regenerating the power developed by the lowering load back into the line. In other words, this point provides an over-synchronous lowering and all loads are lowered with 100- to 105-per-cent speed.

Usually the rotor voltage is not identical with the line voltage, and an auxiliary transformer, shown in Figure 6, has to be provided to supply the proper voltage for the Thrustor motor when it is connected to the rotor of the hoist motor.

The following refinement of the Thrustor lowering control is patent protected for the Whiting Corporation, Harvey, Illinois. For hoists having a mechanical efficiency of 80 per cent or higher it can be assumed that very light loads and even the empty hook overhaul the hoist. In this case after releasing the brake all loads start in the downward direction very positively without any motor torque. This system leaves the rotor circuit entirely open on the first lowering point with no resistors in the circuit and only the Thrustor connected to the slip rings. The hoist motor acts merely as a frequency converter for supplying the speed responsive variable frequency for the Thrustor motor. The advantages are as follows: the creeping speed is lower; the burden on the Thrustor lowering

Figure 2. Exploded view of a Thrustor

Figure 3. Thrustor-operated stop-brake

Figure 4. Thrustor lowering. Brake force versus hoist motor speed

BF—Force on brake shoes by brake spring
TF—Thrust of the Thrustor
BF-TF—Acting force on brake shoes (brake torque)

brake is lessened because there is no additional motor torque to take care of; and finally, there is no necessity for any increase of the conventional rotor resistors, because of the Thrustor lowering control.

As mentioned previously the use of the Thrustor regulating brake is not limited merely to lowering; it can be used without any extra cost or additional apparatus for hoisting as well. With the conventional method of using rotor resistors it is not possible to lift all loads with creeping speed on the first controller point, because either the acceleration on light loads is too great or heavier loads do not start at all. Thrustor control allows creeping speed for all loads. As shown in Figure 4, on the first hoisting point the motor is connected in the up-direction, and the resistor is selected so that the full load starts positively at the first point. The Thrustor at the first point is rotor-connected, thus securing a creeping speed of all loads.

Figure 6 shows the wiring diagram using a conventional drum controller. The same operation also can be accomplished readily by magnetic control and a master switch.

As mentioned previously, with this lowering system a creeping speed of approximately 20 per cent of the full speed is readily obtainable. If this range is not satisfactory and a wider speed reduction is required, this can be achieved by arranging a separate small wound-rotor induction motor as a frequency converter and using the rotor voltage of this auxiliary motor instead of that of the main motor for the Thrustor operation. If this auxiliary motor has the same number of poles as the hoist motor and the belt transmission has a ratio two to one, the frequency obtainable at the slip rings of the small motor is double that of the rotor of the main motor and the obtainable creeping speed with Thrustor lowering and full load is about ten per cent of full speed.

For obtaining good results with the Thrustor lowering there is one requirement which the Thrustor has to satisfy. Because of the hydraulic system used the Thrustor needs an appreciable time for its up or down stroke. Furthermore, some Thrustor types are equipped with means for an additional time delay. Experience shows that the operating time of the undelayed normal Thrustor is satisfactory for crane hoist operations. For Thrustor lowering any additional delay beyond the natural time is entirely undesirable and interferes with a satisfactory operation. The omission of the additional time delay also permits an appreciable simplification of the Thrustor for this special use.

The Mechanical Equipment

There are some requirements on the mechanical part of the brake which have to be satisfied in order to secure a successful operation. In the first place, for the sake of safety in operation a larger size brake is necessary. It is customary to select a normal hoist brake for a braking torque about equal to the full rated torque of the hoist motor. In the case of Thrustor lowering, a brake having a brake torque of 150 to 175 per cent of the full motor torque is recommended. However, as will be discussed later, the burden and wear the Thrustor brake is exposed to with this lowering system is unexpectedly light and not at all excessive.

As far as the mechanical part of the brake is concerned, there are some details which are also present in the design of any general purpose crane brake but which are of even more importance in case of Thrustor Lowering. For instance, when lifting the brake lever it is desirable to obtain a gradually decreasing force at the brake shoes. This means a certain proportionality between stroke and brake torque, and any toggle action in the brake linkage is, for Thrustor lowering, entirely undesirable and disturbing. Furthermore, the clearance of the brake shoes should be equalized and kept as small as possible, barely securing entire freedom for the wheel when the brake lever is in the release position. This requirement is also true for every ordinary crane stop-brake.

To secure best service of the Thrustor lowering, it is particularly important to load the Thrustor by the brake springs as near as possible to its full capacity and to select the Thrustor size adequately; only a small safety margin should be allowed. It is clear that the closer the Thrustor is loaded to its capacity, the better the operation of the lowering control.

It is of interest that at the first performances transient changes of the rotor voltage of the hoist motor were expected which might cause disturbing oscillations of the Thrustor brake during the creeping operation. To prevent these oscillations the Thrustor was not rigidly linked with the brake lever, but cushion springs were inserted to consume the oscillations. Actually, such oscillations were not noticeable and in the future these cushions probably will be omitted.

The specific pressure at the brake lining should be about 30 pounds per square inch. This pressure is a good compromise between excess wear resulting from pressure and excess brake shoe area which would reduce the rate of cooling the drum. In addition, it is advisable to arrange a few holes in the web and to insert some pins to give a better air cooling of the drum surface by air radiation and convection.

Conclusions

With every new development, especially in a field of such intense activities and remarkable achievements such as a-c lowering systems, questions have to be anticipated. Prior to the final conclusions some questions which probably may arise will be discussed.

The first logical questions are, "How badly does the Thrustor lowering affect the brake lining? What influence has this lowering system on the wear of the lining? What is the necessary care for maintenance of the brake and for keeping the proper clearance?" Tests and experience prove that the burden on the

brakes under Thrustor lowering is unexpectedly light. For lowering over greater distances or the entire height, the operator does not use the creeping speed. Rather, he will operate longer distances with over-synchronous lowering during which time the brake is entirely released and will use the creeping speed with the lowering brake where it is needed and this, in general, is only a very short portion of the total life. The difference between the burden on a normal stop-brake and a Thrustor lowering brake actually amounts to only a slightly extended braking period. Experience shows also that there is no appreciable difference in temperature rise, wear, and maintenance between a normal hoist stop-brake and a

Figure 5. The self-adjusted creeping speeds obtainable with Thrustor lowering brake

properly dimensioned Thrustor lowering brake. In this regard it might be instructive to compare the situation of a Thrustor lowering brake with a mechanical load brake. With the mechanical load brake the braking torque is permanently applied during the entire lowering period, regardless of whether the load is lowered with full speed or with creeping speed, or whether the load-brake torque is needed for speed reduction or not. This results in a permanent wear and power loss. On the other hand, with Thrustor lowering the lowering brake is applied only temporarily when needed for creeping speed. This period is relatively short compared with the full lift.

Another question is, "What happens if, in the case of Thrustor lowering, the power supply fails?"

To ascertain the consequences which a failure of the power supply might have on the Thrustor lowering, a series of tests was performed. To make the investigation dependable a 10-ton hoist having a high mechanical efficiency, over 80 per cent, was selected for the test and was loaded with its rated capacity. Two series of experiments were conducted: one with the hoist at rest and attempting to operate the hoist with one line phase interrupted; in the second series one line phase has been interrupted during hoisting and lowering operations.

The results are shown.

LOAD AT REST, ONE PHASE INTERRUPTED

1. Hoisting, on creeping point—Thrustor motor didn't start and brake remained closed. No movement of the load.

Hoisting, on other points—the same.

Lowering, creeping points—the same.

Lowering, over synchronous point—the same.

ONE PHASE INTERRUPTED WHILE HOISTING OR LOWERING

Hoisting, creeping point—Movement stopped immediately.

Hoisting, other points—Movement stopped immediately.

Lowering, creeping points—Movement stopped immediately.

Lowering, over-synchronous point—This is the case of ordinary lowering and has nothing to do with Thrustor Lowering. The Thrustor motor kept on running but with reduced speed, thus applying the brake partially. The hoist motor continued lowering but with a speed far below synchronous. In this case the Thrustor brake offered an appreciably higher degree of safety than the ordinary solenoid, which might remain completely lifted, even with one phase interrupted.

A third question which might arise is, "What is the behavior of the Thrustor lowering system as far as the inching operation is concerned, a vitally important feature of every hoist control." In this regard this system is especially convenient. As mentioned previously, all loads start up or down with the creeping speed on the first controller point, which facilitates exact inching.

Now to the question of how far the Thrustor lowering satisfies the general requirements for crane hoists which have been mentioned previously. It can be said that the Thrustor lowering meets all the requirements remarkably close.

The table showing the main characteristics of the various a-c lowering systems can be extended now to item 10 for the Thrustor lowering.

Lowest speed at lowering full load 25 per cent without or 10 per cent with frequency conversion.

Lowest speed at lowering light loads 10 per cent without or 5 per cent with frequency conversion.

Lowest speed at hoisting full load 10 per cent or 5 per cent.

Lowest speed at hoisting light loads 25 per cent or 10 per cent.

Current consumption—low.

Initial cost—conveniently low, approximately 125 per cent.

Safety in operation—best.

Inching—best.

However, there are certain limitations in the use of the Thrustor lowering which have to be recognized in order to avoid disappointment. The cases in which the Thrustor lowering does not especially qualify are as follows:

Where a creeping speed in the downward direction lower than 10 or 25 per cent is essential. This might be the case with some high speed hoists.

Where the variations of creeping speed at different loads are objectionable.

Where more speed steps between creeping and full speed are important.

Where regular inspection and maintenance

Figure 6. Wiring diagram of a Thrustor lowering control

of the brakes at reasonable intervals cannot be expected.

In general Thrustor lowering is very satisfactory because of its reasonable speed range, simplicity, safety in operation, and low cost.

Finally, one occasional advantage of the Thrustor lowering has to be mentioned. Existing crane hoists can be equipped very readily with this system without difficulties and without great expense.

Discussion

G. W. Heumann (General Electric Company, Schenectady, N. Y.): The author has described for the first time in this country a system of a-c crane hoist control which has found a considerable number of practical applications both here and abroad. To the best of our knowledge, the first commercial installation of a Thrustor load brake was made on a harbor crane near Berlin, Germany in 1935. Since 1941, several hundred boom-type cranes in shipyards and a number of cranes of the traveling type equipped with Thrustor load brakes have been built in this country.

Thrustor load brake control should be considered as a means to decelerate a load from full lowering speed to landing speed. The slow speed obtainable with the load brake should not be used to lower loads over a considerable distance on high-lift hoists, as this would impose an excessive duty on the brake. A certain amount of caution must be exercised by the operator when using the creeping speed point.

When considering the Thrustor load brake system, it must be borne in mind that adjustment of the motor secondary resistor has very little effect on the lowering speed with an overhauling load. The amount of secondary resistance used has a pronounced effect on the kick-off torque which the motor is able to develop, but the effect on the lowering speed under normal load is of no practical consequence.

All energy absorbed by the brake must be dissipated as heat by the brake wheel, and its heat-dissipating ability is the limiting factor determining the selection of brake size for a given application. The author states in his paper that a Thrustor load brake should have a rating of 150 to 175 per cent of motor full-load torque. It would be interesting to know on what grounds this conclusion has been reached. It has been our experience that Thrustor load brakes should be selected for a rating of 200-per cent motor full-load torque.

E. L. Schwarz-Kast: The Thrustor lowering system as pointed out by G. W. Heumann, is not new and has been used in Europe for several years. This paper was written as the result of an installation made in this country in 1939. It is believed that this was the first of its kind in this country.

Heumann's remark, that adjustment of the secondary resistor has very little effect on the lowering creeping speed with an overhauling load, is correct, but it is likewise true, and this is the more important fact which must be kept definitely in mind too, that the use of proper secondary resistor is of great influence on the burden and wear of the Thrustor brake. At lowering overhauling loads with creeping speed the brake has to take over the torque of the load and, in addition, to develop the necessary load for the motor to obtain creeping speed with the secondary resistor in the circuit. The correct rotor resistor for the minimum possible burden and wear on the brake is as follows:

For lowering—The motor must safely start the empty hook in the lowering direction. If the weight of the empty hook is heavy enough to overhaul the hoist, the rotor circuit can remain entirely open (rotor resistor infinite).

For hoisting—The motor must safely start the full load in the upward direction.

It is clear that a too low secondary resistance at lowering with creeping speed will increase the burden and the heat to be dissipated by the brake appreciably.

The recommendation made in the paper, that a Thrustor lowering brake should have a rating of 150 to 175 per cent of full motor torque, was based on actual tests made with a 10-ton hoist. Two series of 200 consecutive stops were performed in a row: one series of normal stops and the others with preceding creeping speed during a generous amount of time. It was found that the temperatures at the brake lining in both cases were nearly the same with a normal stop brake rated 100 per cent and a Thrustor lowering brake rated 150 to 175 per cent of full motor torque. The difference in brake rating obtained by the author and that obtained by Heumann may be because of differences in the secondary resistors used.

Dynamic Braking by Self-Excitation of Squirrel-Cage Motor

A. SRINIVASAN
NONMEMBER AIEE

M. A. THOMAS
MEMBER AIEE

Synopsis: This paper describes a method for calculating the speed–torque curve of a squirrel-cage induction motor when static capacitors are used to produce dynamic braking. The method is simple yet sufficiently accurate for the purpose of selecting equipment for any normal application. The advantages and disadvantages of this method of braking control are compared with those of other methods in use for squirrel-cage motors.

THE USE of static capacitors to produce self-excitation of an induction machine is well known. A number of engineers have realized that this method could be used for dynamic braking, but little application of the principle has been made. If external resistors are connected in parallel with the capacitors, a very great increase in the braking torque can be produced. There are several advantages to be gained by this scheme of braking. A large part of the kinetic energy of the rotating system is dissipated in the external resistors. Braking torque is independent of any power supply. Part or all of the capacitors required may be used during normal motor operation to improve the power factor. The maintenance of mechanical brakes is reduced to a minimum and complicated switching equipment is eliminated. A major disadvantage is the rapid decrease of braking torque as the speed of the motor decreases. In spite of this fact, there are numerous applications of motor control where a careful study of capacitor braking would seem desirable.

Several papers have appeared in technical publications[1,6] in which mention is made of the capacitor braking scheme. So far as the authors are aware, there is no information available as to how the braking torque of a given motor, capacitor and resistor combination may be predetermined. An attempt has been made in this paper to devise a method for calculating the torque–speed characteristic with a minimum of experimental data concerning the motor. A simple graphical scheme is proposed to determine the operating conditions at any selected speed and an approximate value of braking torque is calculated easily. The results of experimental tests conducted on a standard squirrel-cage motor are shown to agree reasonably well with the theoretical calculations.

Comparison of Braking Methods

At least four methods for applying a braking torque to a squirrel-cage induction motor and its load have been discussed in technical articles dealing with the problem of rapidly bringing the motor and its driven load to a stop.

These methods are

1. Mechanical brake.
2. Plugging.
3. Application of direct current to the stator.
4. Induction generator action by means of capacitive excitation.

A brief description and comparison of these schemes will be desirable to show the possible field of application of the method to be described in some detail in this paper.

The mechanical brake, applied by a spring and released by a solenoid operating in parallel with one phase of the motor, provides the simplest type of braking control. It has the advantage that all of the energy absorbed by the brake is dissipated external to the motor. The motor and load are held in position at standstill and this feature makes the mechanical brake an indispensable part of any braking scheme which must provide holding torque at zero or very low speeds. Applications requiring frequent stopping of loads having considerable kinetic energy are likely to result in excessive wear and maintenance cost on a mechanical braking system. Such applications warrant a study of the several electric systems to determine if the advantage to be gained will justify the additional cost and circuit complication of the electrical methods.

Figure 1. Typical speed–torque characteristics for several types of braking control

A—Mechanical brake
B—Plugging
C—Direct current applied to stator
D—Capacitive braking

Plugging of a 3-phase squirrel-cage motor is accomplished by simply interchanging any two of the supply lines. The surge of current in stator and rotor is somewhat more severe than at starting unless a reduced voltage is provided. For loads having only a small amount of friction torque, the energy which is dissi-

The authors wish to acknowledge with thanks the help of Doctor L. T. Rader, head of the department of electrical engineering, Illinois Institute of Technology, for the suggestion of the problem and for providing all facilities for conducting the experiments in the laboratory.

Figure 2. Equivalent circuit of an induction motor

pated as heat in the rotor in braking the load to standstill is nearly three times[3] the kinetic energy of the motor and load. This extreme heating of the rotor would seem to limit the application of plugging of squirrel-cage motors to cases where either low inertia or infrequent stops would make it practical. An additional complication is the necessity of an automatic switch of some kind to remove power at the instant the motor stops, otherwise the motor and load will be brought quickly to full speed in the opposite direction. The magnitude of the braking torque can be controlled only by the application of an adjustable voltage during the braking period.

Application of direct current to one phase of the stator of a squirrel-cage motor will provide a braking torque which can be adjusted quite easily. Heating energy equal to the kinetic energy of the motor and load will be produced in the rotor for applications having a small friction torque. The braking torque will vary with the speed of the motor and in general will follow a characteristic similar to that shown in the diagram of Figure 1.

The difficulty of dissipating any great amount of energy either in a mechanical brake or in the rotor of the squirrel-cage motor has led several engineers to investigate the possibility of operating a motor as an induction generator during the braking procedure and thereby make possible the transfer of power from the machine to an external resistor. Considerable study has been made of the operation of an induction machine with self-excitation supplied by static capacitors.[4] Most of the published information, however, deals with operation at a constant frequency and little has been done on the varying frequency problem of dynamic braking. The self-excitation is known to decrease rapidly with decrease in speed of the motor. However, if braking can be accomplished even to one-half speed, three-fourths of the kinetic energy of the rotating parts will have been dissipated. The application of the method of braking has been handicapped by the fact that no very simple or reliable method has been available for predetermining the speed–torque characteristic which will result from a given motor, capacitor, and resistor combination. The purpose of this paper is to describe a method by which this speed–torque characteristic can be calculated with fair accuracy and with a minimum of test data concerning the motor. Typical speed–torque characteristics for the four methods of braking are shown in Figure 1. A determination of the speed–time characteristic for any given load requires the additional knowledge of only the WR^2 of the load and motor and the load torque. A general method for solution of this problem is given in several standard textbooks[2] dealing with motor applications.

Conventions and Assumptions

The conventional equivalent circuit of the induction motor as shown in Figure 2 will be used as the basis of the analysis. The copper loss in the rotor circuit, however, will be neglected and the current-voltage characteristic of the exciting susceptance B will not be assumed a constant but must vary in accordance with the no-load test data for the motor. The particular volt-ampere characteristic for any motor will depend upon the saturation of the iron of that machine. The wave form of the voltage is nearly sinusoidal[2] and little error is introduced by such an assumption. The frequency is assumed to be that determined by speed alone without regard to slip. This will introduce considerable error at low voltages where the generator action is disappearing, but does permit a simple graphical solution for the operating conditions. A more exact method based on a cut and try solution is available[4] if thought necessary. The voltage drop in the primary impedance caused by the in-phase component of the current through the load resistor is neglected. The very considerable tolerance in the capacitance of capacitor units makes a simple solution sufficiently accurate for the purpose of specifying the capacitors for a given application.

These assumptions reduce the equivalent circuit to the approximate form shown in Figure 3. The symbols have the following meaning:

R_1 = stator resistance in ohms per phase to neutral
X_1 = stator leakage reactance in ohms per phase to neutral, at normal frequency
B = exciting susceptance
C = equivalent capacitance in farads per phase to neutral
R = equivalent resistance of load resistor in ohms per phase to neutral

The actual values of C and R which are connected line to line (and not line to neutral) are respectively one-third and three times their equivalent values as shown in this circuit.

V = terminal voltage to neutral or by assumption of balanced sinusoidal condition is line voltage divided by $\sqrt{3}$
E = air gap induced voltage to neutral
I_1 = primary current per line assumed positive as shown by the arrow

The curve of Figure 4 shows the volt-ampere characteristic of the motor. Data for this curve were obtained by operating the motor at normal speed and without load. A 5-horsepower 850-rpm 220-volt 3-phase 60-cycle squirrel-cage motor was used in the sample calculations and the same motor was used for the experimental checks.

Analysis of the Problem

Consider first the approximate circuit of Figure 3 without the braking resistor. The current I_1 will lead the voltage V by 90 degrees because it is merely the current taken by the capacitor C. The current taken by the motor when running idle with voltage V applied will be near this same current. The voltage E may be expressed as

$$E = V + I_1(R_1 + jX_1)$$

as shown in the vector diagram of Figure 5.

$$E = V - I_1X_1$$

because the component I_1R_1 is at right angles to V and contributes little to the magnitude of E.

In general the air gap induced voltage is a function of flux and speed.

$$E = f(\phi, N)$$

where ϕ and N are flux and speed respectively. Then

$$\phi = g(E/N)$$

The no-load current I_n depends on the flux and hence

$$I_n = h(E/N)$$

Because

$$V = E + I_1X_1 \text{ (numerical addition)}$$

Figure 3. Approximate equivalent circuits for the determination of operating conditions

Figure 4. No-load characteristics of induction motor

A—Curve connecting the total no-load watts and line-to-line volts

B—Curve connecting the line current and the line-to-line volts

then we may say that

$$I_n = F(V/N)$$

Either air gap voltage or terminal voltage from test data may be plotted against no-load amperes to represent the given relation. In Figure 6 is shown the curve plotted from data taken on the 5-horsepower motor.

Data taken with capacitive excitation at various speeds checked very accurately with those taken from the usual no-load motor test. The current through the capacitor is

$$I_c = V2\pi fC$$

But

$$f = \frac{P}{120} N(1-S)$$

In the analysis, if slip S is neglected,

$$I_c = \frac{V}{N} \frac{2\pi P N^2 C}{120}$$

where P = number of poles for a given value of speed N and capacitor C this is an equation of a straight line and may be drawn on the plot of Figure 6. The intersection of the curve and straight line will give the no-load operating condition of current and voltage for this speed. Several lines with different slopes representing different speeds or capacitances may be drawn. The slope of the line for a fixed capacitance is seen to vary with the square of the speed.

The power absorbed by the machine from the kinetic energy now may be calculated as the sum of the following three parts:

1. The power to the resistor R is

$$P_r = 3V^2/R.$$

2. The power to R_1 is

$$P_{r1} = 3I_1^2R_1.$$

3. The friction, windage, and core loss P_e read from the test curve obtained at the same time as the no-load saturation curve and shown on Figure 4.

$$P_{\text{Total}} = P_r + P_{r1} + P_e$$

The retarding torque then is obtained from the usual equation

$$T = \frac{7.04 \times P_{\text{Total}}}{N} \text{ pound-feet}$$

The deceleration time is a function of the WR^2 of the motor and driven machines and is also dependent on any friction load which may be present.

A Typical Example

The no-load characteristic of a 5-horsepower 8-pole 60-cycle 220-volt 3-phase squirrel-cage induction motor as obtained from tests is given in Figure 4. The resistance per phase of this motor is 0.375 ohms at 65 degrees centigrade. A calculation of the torque developed with a capacitance of 200 microfarads and a resistance of 120 ohms per phase connected in delta across the lines will be made. The equivalent C and R in the line to neutral circuit of Figure 3 are 600 microfarads and 40 ohms respectively. The current in the capacitor is given by

$$I_c = \frac{V}{N} \times \frac{2\pi P N^2 C}{120}$$

$$= \frac{V}{N} \times N^2 \left(\frac{2\pi \times 8 \times 600 \times 10^{-6}}{120} \right)$$

For $N = 900$ rpm, this reduces to

$$I_c = 203(V/N)$$

This straight line then is plotted in Figure 6 and intersects the curve at $V/N = 0.230$ and $Ic = 46.5$. The voltage to neutral then is $V = 0.230 \times 900 = 206$ volts, or 350 volts line to line. The several power components are

$$P_r = 3 \times \frac{206^2}{40} = 3{,}190 \text{ watts}$$

$$P_{r1} = 3 \times 46.5^2 \times 0.375 = 2{,}430 \text{ watts}$$

From Figure 4, for a line-to-line voltage of 350,

$$P_e = 2{,}200 \text{ watts}$$

$$P_{\text{Total}} = P_r + P_{r1} + P_e = 7{,}820 \text{ watts}$$

The retarding torque

$$T = \frac{7.04 \times 7{,}820}{900} = 61.2 \text{ pound-feet}$$

In a similar way, the torques for speeds of 800, 700, 600 rpm are obtained. The speed at which braking action ceases can be determined by drawing the tangent to the curve in Figure 6. From the slope of the line this speed was found to be 465 rpm. This is the critical speed for the capacitance chosen. The values of torque, voltage, and current for the different speeds are plotted in Figure 7.

An experimental check was made by driving the motor at the different speeds by means of a d-c dynamometer. At speed above the critical speed, the machine rapidly built up voltage when connected to the capacitor-resistor combination. Values of torque, voltage, and current were obtained for each speed. The experimental values are shown by small crosses on the plot of Figure 7; as can be seen, the agreement is satisfactory in most cases.

Solution for Speed–Time Relation

The net friction or overhauling torque of the load as a function of speed and the total WR^2 of the rotating system must be known. Then with the braking torque obtained the net retarding torque T_r will be

$$T_r = T - T_L$$

where T_L is the torque produced at the shaft of the motor by the driven machine. T_r will be represented by a curve and in general will be a function of speed alone.

Figure 5. Vector diagram of induction machine at no-load

The usual equation relating T_r and time is

$$(\text{Average})\, T_r = \frac{WR^2 N}{307.8(t)}$$

where N is the change in speed occurring in t seconds. In better form

$$T_r = \frac{WR^2}{307.8} \frac{dN}{dt}$$

expresses the torque as a function of the rate of change of speed.

Figure 6. Graphical construction for operating conditions at various speeds

Solving the foregoing equation for time t,

$$t = \frac{WR^2}{307.8} \int_{N_1}^{N} \frac{1}{T_r}\, dN$$

As outlined in reference 2, the integration can be made by a graphic tabular process to obtain the time t for speed to change from N_1 to any other value N.

Conclusions

The capacitor braking scheme has many desirable features for dynamic braking of squirrel-cage induction motors. Although the braking action does not persist till the motor stops, it does dissipate the greater part of the kinetic energy of the rotating system. The analysis proposed in this paper will permit satisfactory prediction of the speed–torque characteristic of any proposed motor and capacitor combination. From the test results it appears that capacitors having a kilovolt-ampere rating of about three times the exciting kilovolt-amperes of the motor will produce an initial retarding torque of double the full load torque. The current and the voltage developed by self-excitation are considerably above the rated values for the motor. The speed, however, is reduced rapidly by this large torque and no damage should result to the motor or associated equipment. A part, or perhaps all of the capacitors needed, can be used for power factor correction during normal running of the motor.

No Discussion

Dynamic Braking of a Single D-C Series Motor

JOHN D. LEITCH
MEMBER AIEE

Synopsis: Various methods employed in obtaining dynamic braking with a single d-c series motor are discussed. Emphasis is placed on the control of the dynamic braking contactors where braking is required on power failure irrespective of direction of rotation of the motor. The use of polarized spring-closing contactors offers a simple and reliable solution when ruggedness of the equipment is important. Methods of obtaining graduated dynamic braking automatically also are considered.

THE d-c series motor is used widely in steel mills particularly on such auxiliaries as roller tables, blooming mill screwdowns, manipulators and side guards, and on overhead traveling cranes. Many drives require automatic stopping in the event of power failure or the tripping of the overload relay. Such stopping may be obtained by the "setting" of a magnet-operated friction brake, by electric braking within the motor itself, or in many cases, by a combination of both. When electric or dynamic breaking is obtained automatically on power failure, it is referred to as "emergency dynamic braking" to distinguish it from "service dynamic braking" where the necessary switching is controlled by the operator.

Dynamic Braking in One Direction Only

It is a simple matter to provide dynamic braking in only one direction with a single series motor. Figure 1 shows the power circuits of a series motor and a typical reversing controller. Two pairs of reversing contactors, *F* and 1*F* and *R* and 1*R*, a negative line contactor *M*, and an accelerating resistance constitute the essential parts of the controller (the acceleration contactors are omitted from the diagram). Two spring-closing contactors *FB*1 and *FB*2 are shown with their contacts located between the field and armature terminals and including within the loop-circuit so formed, a suitable dynamic braking resistor. On power failure the reversers and the negative line contactor open while the spring closers close.

If the motor is traveling forward (*F* contactors closed) at the instant of power interruption, the counter electromotive force will be in direction 2–1 and current will flow from the armature at 1 through the field in direction 3–4, through the dynamic braking resistor, back to the armature at 2. Thus the current is reversed in the armature and maintained in the same direction in the field, a sufficient condition for developing a braking torque. It can be seen easily that if the motor is traveling in the reverse direction at the instant of power failure, this circuit does not provide dynamic braking as the current is reversed in both the field and the armature.

Dynamic Braking in Both Directions

Obviously a second pair of spring-closing contactors is required to provide dynamic braking in both directions. Figure 2 shows the addition of these two contactors, *RB*1 and *RB*2.

It is necessary that only one pair of spring-closing contactors close on power failure, the *FB*1 and *FB*2 pair when the motion is in the forward direction and the *RB*1 and *RB*2 pair when the motion is in the reverse direction. Various schemes of control have been employed to accomplish this result, the most common being some form of a mechanical latching-out relay which holds out the appropriate pair of spring closers. A typical arrangement of a latching-out relay with four spring closers is shown schematically in Figure 3.

The four spring closers *FB*1 and *FB*2 and *RB*1 and *RB*2 are shown with their contacts open (armatures closed). Each pair is shown with a tie rod which ties the armatures together. The latching-out relay has two coils *RF* and *RR* and a T-shaped armature pivoted at *A*. When the motor is rotating in the forward direction, the coil *RF* is energized and the T-shaped armature engages the tie rod of the contactors *RB*1 and *RB*2 through the hole *C* in the armature. Thus, in the event of power failure while the motor is rotating in the forward direction, *FB*1 and *FB*2 would be allowed to close their contacts while *RB*1 and *RB*2 would not.

It is apparent that some additional control means must be provided which will assure the energization of the appropriate coil *RF* or *RR* of the latching-out relay according to the direction of rotation of the motor. The simplest means is a directional switch mechanically connected to the motor shaft. Figure 4 shows a portion of the control circuit with a directional switch and a latching-out relay.

This method has been used extensively and is free from trouble so long as the directional switch and the latching-out relay are kept in good order. There are some objections to the use of a directional switch from a maintenance point of view, and the latching-out relay is not without mechanical difficulties.

It might be thought at first glance that the directional switch could be elimi-

Paper 47-21, recommended by the AIEE committee on industrial control devices for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 6, 1946; made available for printing December 3, 1946.

JOHN D. LEITCH is with The Electric Controller and Manufacturing Company, Cleveland, Ohio.

nated by using auxiliary contacts on the reversers as in the circuit shown in Figure 5. As long as the master switch position is in agreement with the direction of rotation of the motor, the proper coil *RF* or *RR* will be energized. But should the operator "plug" the motor just before power failure, no dynamic braking would result because of closure of the wrong pair of spring closers. In other words, it is essential that the latching-out relay be controlled by the direction of rotation of the motor irrespective of the position of the master switch.

A voltage relay *VR*, having its coil connected across the motor armature, may have its normally closed contacts added to the circuit of Figure 5 as shown in Figure 6. After *VR* has picked up at a low motor speed, there will be no change in the position of the armature of the latching-our relay as long as the motor continues to travel in the same direction even though it is plugged. There is one disadvantage however in that during "drifting" with the master on the "off" point the *VR* relay will open to close its contacts. If the operator then should plug the motor, the latching-out relay would be reversed and should power fail under these conditions, no dynamic braking would be obtained. It is therefore necessary to provide a "teaser field" connection during drifting. This is done by connecting a resistance in series with a contactor between the positive line and the field on Figure 2. This contactor must be energized on the "off" point of the master along with the *M* contactor to provide a current through the field during drifting. This prevents relay *VR* from dropping out during drifting and the difficulty regarding power failure after or during plugging does not arise. The use of a voltage relay in conjunction with the electric interlocks on the reversers suggests the use of a polarized relay, with its coil connected across the armature. The contacts of the polarized relay can be considered identical to those provided by the directional switch shown in Figure 4. Sensitive polarized relays are available which will pick up at a low voltage and hold closed to a very low voltage. Such a relay requires an additional relay to insert a protective resistor in its coil circuit against overheating as the voltage across the motor armature increases with speed. A teaser field contactor and resistor are not necessary with the polarized relay because of its low drop-out voltage.

Polarized Spring Closers

A polarized relay used in conjunction with a latching-out relay is very satisfactory from a circuit point of view, but available polarized relays are far too delicate for use on heavy equipment such as that encountered in a steel mill. The method still has the disadvantage inherent in a mechanical device such as the latching-out relay. If the spring-closing contactors themselves could be polarized, the need for the latching-out relay would disappear and the control would be entirely electrical.

Referring to the circuit in Figure 7, there are four spring closers, *FB*1 and *FB*2, *RB*1 and *RB*2, as shown in Figure 2. One pair only must close its contacts to provide dynamic braking in one direction, the other pair only if the motor is rotating in the reverse direction. Each of the four spring closers has two identical coils referred to as the operating and polarizing coils. The operating coils of all four contactors are connected in series with each other and with a resistor *C* across the control voltage, while the four polarizing coils are connected in parallel and the group connected in series with a resistor *B* across the motor armature.

The system of connecting the two groups of coils is that, for the forward direction of motion, the polarizing coils of the *FB* pair of contactors will be in opposition to the operating coils while both coils on each of the *RB* contactors will be connected additively. Thus, on power failure, with the motor rotating in the forward direction, the *FB* contactors will drop out to close their contacts while the *RB* contactors will be held open by the polarizing coils. In the opposite direc-

tion of motion the *RB* contactors will close their contacts while the contacts of the *FB* pair will remain open.

The spring-closing contactors are somewhat special in that they have a magnetic circuit of low reluctance, and consequently very low drop-out ampere-turns. The coils are good for about 30 volts continuously and must be protected by resistors, hence the use of resistor *C* in the operating coil circuit and the resistor *B* in the polarizing coil circuit. Figure 7 shows two voltage relays *VR*1 and *VR*2 and a time-delay relay *TD* for inserting the protective resistors.

With the master on the "off" point, the *TD* relay is energized through the normally closed auxiliary contacts on *FB*1 and *RB*1. The normally open contacts on *TD* close to short-circuit the resistor *C* permitting the operating coils to open the contacts of all four spring closers. Relay *TD* is de-energized and after a short time delay opens its contacts to insert resistor *C*. The contactors remain closed magnetically with resistor *C* in the circuit. Thus on the "off" point the *UV* relay is closed, the contacts of the four spring closers are open, and the time-delay relay is de-energized.

When the master is moved to any running point, the motor accelerates; relay *VR*2 is the first to pick up inserting protective resistor *B* in series with the polarizing coils of the spring closers. Resistor *B* not only protects the polarizing coils thermally, but also limits the ampere-turns to a value somewhat below that provided by the operating coils. Otherwise one pair of spring closers (that with the coils in opposition) would drop out when the armature voltage increased sufficiently. Resistor *B* will take care of a counter voltage as high as 200 volts but during plugging when the voltage rises above this value, some additional precaution will be necessary. This will be discussed later when a complete controller is described.

Since relay *VR*2 must pick up at a low voltage, it requires an intermittent duty coil. This coil is protected by a second voltage relay *VR*1 which picks up at a somewhat higher voltage to insert resistor *A* in the *VR*2 coil circuit.

On power failure with the motor running in either direction, all contactors drop out magnetically except the appropriate pair of spring closers whose contacts are held open by the polarizing coils. During the short interval from the instant power fails until the dynamic braking circuit is established, this pair of polarizing coils is energized by the low counter voltage obtained from the residual magnetism in the motor field to produce a flux in the contactors in the same direction as their residual flux. The closing of one pair of spring closers removes the polarizing coils from the circuit by the opening of one of its own interlocks. This increases the voltage applied to the remaining pair of polarizing coils since the voltage drop across resistor *B* is reduced. As the motor slows down, relay *VR*2 drops out first (resistor *A* is in series with the coil of *VR*2 as *VR*1 does not open until a much lower voltage is reached). Opening of *VR*2 by-passes resistor *B*, thereby again increasing the voltage to the polarizing coils of the two remaining spring

Figure 11. Graduated dynamic braking, series coil spring closer

closers and assuring that their contacts will be held open until the motor slows down to a very low speed. When the voltage across the armature reaches the drop-out value of $VR1$, it will open to bypass resistor A in series with the $VR2$ coil, but $VR2$ will not pick up again at this voltage.

Obviously a teaser field contactor and resistor should be added to Figure 7 to assure a voltage across the polarizing coils and the protective relays during drifting with the master on the "off" point.

Graduated Dynamic Braking

For a given series motor the dynamic braking torque is determined by the speed of the motor at the instant of power failure and by the resistance of the dynamic braking circuit. For reasons of commutation there is a lower limit to the value of resistance that may be used, the choice depending on the maximum anticipated speed. The dynamic braking torque falls off rapidly with motor speed, and if quick positive stopping is desired, it is necessary to short-circuit some of the dynamic braking resistor as the motor slows down.

Figures 8 to 11 inclusive show a variety of methods that have been employed to obtain graduated dynamic braking. Figure 8 shows the use of a spring-closing contactor DB with its coil connected across the motor armature and its normally closed contacts across a portion $R2$-$R3$ of the dynamic braking resistor. Such a contactor can be designed with a drop-out voltage of about 50 volts. Thus when the armature voltage falls to this value during deceleration, the contacts will close to short-circuit resistor section $R2$-$R3$ and increase the dynamic braking torque. Should power fail before the voltage across the armature reaches the pickup value of DB there would be no harm in braking with the lower value of resistance $R1$-$R2$.

On actual test, contactor DB drops out at the instant power fails because of loss of field, but picks up again as the voltage across the armature builds up after the closure of the spring-closing contactors FB or RB. This momentary closure of DB places a definite limit on the value of resistor $R1$-$R2$ from a commutation point of view.

As the motor slows down and DB closes its contacts, the voltage across the armature rises and DB may open and close its contacts two or three times during the interval in which the motor is being brought to rest.

Figure 12. Plugging-reversing controller for single series motor with service and emergency graduated dynamic braking

For maximum dynamic braking torque at low speed, it is desirable that resistor *R1-R2* be as low in value as possible. It is therefore desirable that the *DB* contactor remain open during the short interval between loss of power and building up of dynamic braking current. This can be accomplished by using a low voltage coil on *DB* and protecting it with a resistor, at the same time making its magnetic circuit of low reluctance so that its drop-out voltage is but a fraction of a volt. This requires a voltage relay *VR* to insert the protective resistor as shown in Figure 9.

The pickup voltage of contactor *DB* must be below that of relay *VR* so that *DB* will open its contacts before *VR* inserts the protective resistor in series with the *VB* coil. When *VR* picks up, *DB* must continue to holds its contacts open after the protective resistor is inserted. This means that the drop-out voltage of *DB* with protective resistor inserted must be below the pickup voltage of *VR*. With the pickup voltage of *VR* about 70 volts and the drop-out voltage of *DB* (with protective resistor inserted) about 50 volts, this condition is met.

On power failure, the voltage across the armature drops for an instant, *VR* will drop out quickly to by-pass the *DB* protective resistor permitting *DB* to hold its contacts open down to a fraction of a volt. Because of the sluggishness of *DB* in opening magnetically under these conditions, it does not close its contacts during the short interval of low voltage. This permits a lower value of *R1-R2*.

The drop-out voltage of *DB* with protective resistor is about 50 volts. Hence as the motor decelerates to a speed corresponding to this voltage, *DB* drops out to close its contacts. The pickup of *DB* with protective resistor is of the order of 200 volts or more. Hence it will not pick up again as the voltage across the armature increases with increase in dynamic braking current. When the voltage across the armature falls still lower, *VR* relay will drop out to by-pass the *DB* protective resistor. By choosing the drop-out voltage of *VR* below the pickup voltage of *DB* without protective resistor, contactor *DB* will not open its contacts again. Thus the flutter of contactor *DB* during deceleration is eliminated.

It is not intended to present all the possible methods of obtaining graduated dynamic braking automatically. Two other methods are however of interest. The first which has been used for a number of years, employs a series relay and a normally open shunt contactor with its coil connected across the armature as shown in Figure 10. The coil of contactor *DB* is connected in series with the normally closed contacts of relay *SR* and the normally closed auxiliary contacts of the spring closers *FB* or *RB*. Thus when the motor is running the *DB* coil is de-energized. This permits the use of a low voltage coil on the *DB* contactor without need for a thermal protective resistor. The series relay *SR* has its coil connected in the dynamic braking loop.

When power failure occurs, there is a race between the *DB* contactor and the *SR* relay as the current in the dynamic braking loop builds up simultaneously with the voltage across the armature. The small series relay will respond more rapidly than the larger contactor. Consequently *DB* cannot close its contacts until the dynamic braking current has fallen to a value corresponding to the drop-out of the *SR* relay. When the *SR* relay drops out to close its contacts, *DB* will close its contacts to short-circuit part of the dynamic braking resistor *R2-R3*. The current will rise to a value depending on the ratio of *R2-R3* to the total resistance of the loop circuit. If this ratio is high, *SR* may pick up again and drop out *DB*. This will be repeated until *SR* finally stays out and *DB* stays closed. Contactor *DB* must be provided with a low voltage coil and a low reluctance magnetic circuit so that it will stay closed to a low value of voltage.

The pickup voltage of *DB* must be below that corresponding to the drop-out current of relay *SR;* otherwise *DB* would never pick up. Therefore the pickup voltage of *DB* must be still lower relative to that corresponding to the pickup current of relay *SR*. This is on the unfavorable side as far as *SR* winning the race with *DB* is concerned and must be offset by quicker response of *SR* to the rapid rise of current and voltage in the loop circuit immediately following power failure.

The second of the two methods is an exceedingly simple one in that the series relay and shunt contactor of Figure 10 are replaced by a single series coil spring-closing contactor as illustrated in Figure 11. The advantage of this circuit is its simplicity and its freedom from electrical interlocks and protective resistors. The series coil spring-closing contactor has a heavy strap coil of but a few turns and this along with the fact that it is energized only during dynamic braking makes the circuit exceedingly safe from a loss-of-coil point of view.

The one disadvantage of the circuit lies in the possible high inrush of current during dynamic braking just before the spring closer opens its contacts. This places a lower limit on the value of resistor *R1-R2*. The very rapid response of the spring closer to the rapidly rising current makes the duration of the peak current very short. As the motor slows down, *DB* will close its contacts to short-circuit resistor section *R2-R3* and, depending on the extent of the change in the circuit resistance, *DB* may pick up again repeating the operation a number of times as the motor comes to rest. A number of installations using this means of obtaining graduated braking recently have been put in service and no difficulty has been encountered by the fluttering behavior of the contactor during deceleration of the motor.

Plugging Reversing Controller Providing Graduated Service and Emergency Dynamic Braking

To illustrate the application of some of the various schemes set forth, the elementary diagram for a complete plugging reversing controller is shown in Figure 12. This controller provides graduated emergency and service dynamic braking from either direction of motion. The control was designed for use on a coal bridge trolley where the trolley is driven by cables from a motor located on the bridge structure. Magnetic brakes cannot be used without excessive abuse of the cables, and it is desirable that the deceleration of the trolley be as smooth as possible.

The controller is a standard plugging reversing controller with the addition of four polarized spring closers *FB* and *RB* for dynamic braking, a teaser field contactor *TF*, and current limiting resistor. Three voltage relays *VR1*, *VR2*, and *VR3* and a time-delay relay *TD* are included for protection of intermittent duty coils. Two additional spring closers provide graduated dynamic braking and a second master switch is used for service dynamic braking.

It is not necessary to describe completely the operation of the controller as it is a standard controller with additional features which just have been described.

The service braking master provides two points of braking. The first point opens the reversers and permits the appropriate pair of spring closers to close. The dynamic braking resistance is *R1-R4* on this point. The second point closes *DB1* to by-pass resistor *R1-R2* and increases the breaking torque. A third step of braking is provided automatically by contactor *DB2* as described earlier.

The acceleration and plugging of the motor are controlled in the usual manner. The only special feature occurs during

plugging when it is necessary to offset the increase in ampere-turns in the polarizing coils by short-circuiting resistor D in series with the operating coils. This is accomplished by employing normally closed auxiliary contacts on the plugging contactor P in energizing the time-delay relay TD. After the motor has been plugged to rest and accelerated in the opposite direction, TD will open to again insert the protective resistor D.

Should the main master be moved to "off" point with the service-braking master in the "drift" position, the M contactor remains closed and a teaser field contactor TF closes to provide current in the field. This assures voltage on the voltage relays and the polarizing coils of the four spring closers. The M and TF contactors remain closed until the motor speed drops to a value corresponding to the drop-out voltage of relay $VR1$ at which time they open their contacts to remove the teaser field circuit.

In the event of power failure while running or drifting with the master on the "off" point all contactors and relays fall out except the appropriate pair of spring closers and the voltage relays across the armature. Contactor $DB1$ closes its contacts instantly and two steps of dynamic braking are provided automatically by contactor $DB2$.

All of these control schemes have been tested giving results in agreement with the foregoing analyses

No Discussion

Advancements in the Design of Long-Scale Indicating Instruments

R. M. ROWELL
ASSOCIATE AIEE

N. P. MILLAR
ASSOCIATE AIEE

SHORTLY before the war the development of new materials[1] and techniques made it possible to build long-scale instruments for accurate electrical measurements over the widely varying conditions encountered in practice. A complete line of long-scale instruments was designed and built incorporating four new and different mechanisms.[2] These instruments were standardized by the United States Navy for combat vessels as well as for many other naval applications.

Experience gained in the past few years has pointed the way to certain design improvements which seem desirable and which would accomplish the following objectives:

1. Improve the general appearance and ease of reading.
2. Facilitate calibration and adjustments.
3. Improve accuracy under abnormal conditions.
4. Facilitate repairs by making the moving systems more readily removable.
5. Simplify recalibration with existing scales.

The improvements in appearance and readability are described in the following paragraph, while the engineering and design work to accomplish the other objectives are outlined in the description of the individual instruments which follows.

Scale and Cover Design

In the design of modern switchboards considerable attention now is being given to appearance and symmetry as well as to their functional features. The modified instruments therefore have been designed with this fact in mind. With such changes, however, certain features have been incorporated which will aid operators in obtaining quick and accurate readings. Figure 1 shows the appearance of the new line of instruments with plastic covers, although heavy pressed metal covers are available for high-shock applications. The window opening has been beveled to improve readability at sharp angles. The scale numerals have a form and arrangement that make them easy to read, and confusion in associating these numerals with the proper cardinal points is eliminated by wedge-shaped accent marks at these points.

D-C Ammeters, Voltmeters, and Temperature Meters

Improvements in long-scale permanent-magnet moving-coil instruments for d-c use have been directed toward increased permanency of calibration under abnormal conditions and ease of servicing and repair. In such instruments it sometimes is desired to remove the moving system for repair or inspection. This operation usually involves removal and replacement of the center core. This is not serious in the case of conventional 90-degree-scale instruments as any increase in the air gap on one side which affects the torque on the corresponding side of the moving coil results in a decrease in gap on the other side with opposite effect on the moving coil, so that there is no resultant effect on the total torque. On long-scale instruments, however, the moving coils are eccentrically mounted with only one side of the moving coil in the air gap so that any change in the gap affects the scale distribution on both sides. To eliminate the possibility of such distribution changes the magnetic return path is made in a single piece with the center core and the outer ring made of powdered iron sintered in a single mold (see Figure 2). Obviously, this center core must be broken at some point to permit removal of the moving system. Because the magnetic circuit is operated at a high flux density any break in the magnetic core must be made at a point which will have a minimum effect on the total flux density, the stability of the magnet, and the distribution of the scale. Figure 3 shows the magnetic flux paths in this system. It will be noted that the core opens at the top center where it will give the least possible effect because the flux splits at this point to return through the magnet and the outside ring in opposite directions. A small piece of sintered iron is cast onto the frame and fits into the core opening when the frame and moving system are inserted, thus preventing any distortion of scale distribution at this point.

As the electrical losses in this instrument are very low, it has been possible to make most voltmeters with the resistance internal and thus eliminate the rear external-resistance cage. A resistor is provided on the front of the instrument frame

Figure 1. Typical improved design of long-scale instrument

Paper 47-22, recommended by the AIEE committee on instruments and measurements for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 1, 1946; made available for printing December 23, 1946.

R. M. Rowell and N. P. Millar are both with the instrument engineering division, General Electric Company, West Lynn, Mass.

Figure 2. Mechanism of improved d-c instruments

Figure 3. Magnetic circuit of d-c instruments

for adjusting the circuit resistance to compensate for changes which may be made in shunt leads, for example, after the instruments are calibrated originally.

It is felt that this design incorporates the best possible features to obtain high operating torque and torque-to-weight ratio, ease of assembly and repair, and, above all, the most permanent structure possible from the standpoint of mechanical and electrical stability; and a scale distribution that will not change throughout the life of the instrument is assured.

Damping Mechanism for A-C Instruments

All a-c instruments are equipped with an eddy-current damping mechanism of simple construction. It consists of two half-ring Alnico steel magnets with grooves cast in the sides as shown in Figure 4. These two magnets are assembled on the instrument in a circular arrangement directly over a small segmental aluminum disk, which is carried by the moving element. The magnetic circuit is completed through the disk to a soft-iron plate mounted directly below the disk and having the same contour as the magnet. This simple arrangement provides an adequate damping torque throughout 360 degrees of disk movement.

To magnetize these units each magnet is placed in a special magnetizing fixture so designed that a conductor is looped through the grooves in a manner similar to that shown in Figure 5. When a high impulse direct current is passed through the conductor the grooved surface becomes a series of alternate north and south poles. Were it not for the mounting lugs, which are integrally cast with each magnet, the poles would have the same flux distribution. However, the nonuniformity of flux which results does not in any noticeable way affect the over-all damping characteristic. This flux distribution is revealed clearly in Figure 6 by means of an iron-filings pattern taken on such a magnet.

A-C Ammeters and Voltmeters

The use of a long-scale attraction–repulsion iron-vane system for several years has pointed the way to improvements in stability and scale distribution and better control of the latter. In a system comprising four magnetic components, their configuration as well as the spacing between them determine the flux and torque characteristic at any scale point and define the scale distribution of the instrument. Not only is the spacing between the various stationary irons an important factor, but so, also, is the operating radius of the moving vane. To obtain better control of vane dimensions, a new method of mounting was devised in which the mounting bracket was cut from the vane itself and bent over to give a single-piece construction (see Figure 7). This results in better dimensional control radially, and also eliminates any soldering or welding operations on the vane itself with possible introduction of hysteresis effects. The new vane system after final forming requires only a single anneal to bring out its best magnetic characteristics which are no longer jeopardized by subsequent operations.

In the previous attraction-repulsion system, a single repulsion member was used for both ammeters and voltmeters with different attraction irons to obtain the two different types of scale distribution desired. In the new design the two different repulsion irons for ammeters and voltmeters are so shaped as to give the proper scale distribution on the lower half of the scale where their effect is the greatest (see Figure 8). It will be noted that on the ammeter the slope is steeper at the zero end, thus producing a greater torque gradient over the low end of the scale and making possible readings down to ten per cent of full-scale value. On voltmeters, however, conditions are usually different and voltages rarely will vary more than 20 per cent above or below normal established line voltages. The repulsion iron selected for this instrument, therefore, has a straighter slope to produce a gradual opening of the scale from about 20 per cent to the full-scale value, producing a scale which is the most open in the normal operating range. Torque curves (shown in Figure 9), taken at full-scale voltage, indicate the improvement made by the use of the new irons in voltmeters. By straightening these curves any tendency to constriction of the scale distribution around center scale is eliminated.

Improved control of the dimensions and

Figure 4. Cutaway section of magnetic damping system

Figure 5. Sketch showing method of magnetizing damping magnets

Figure 6. Flux pattern of typical damping magnet

position of the stationary attraction system represents another important improvement in this new design. As indicated by the sketch (Figure 7), the inside of each shield that supports the attraction irons is drawn down to a short tubular section in the center. This results in a stiffer shield with little chance of distortion and at the same time adequately supports the inside of the attraction iron and thus preserves its circular contour. Also, it has been found possible to eliminate the slot through the shield previously used to prevent eddy currents. Because of the high specific resistance of the material used, errors from this source are negligible up to 400 cycles.

To obtain greater control of scale distribution, the full scale ends of the attraction irons have been given an increased slope which gives the instrument greater sensitivity in the upper scale region. This permits a greater adjustment of scale distribution by turning the shields to which the attraction irons are attached, thus making it possible to secure a distribution that is substantially uniform over most of the active range. By forming locating ears which rest against the inside of the shield, the spacing between the attraction irons is held to closer dimensions and thus the duplication and control of scale distribution are facilitated.

Wattmeters and Varmeters

In the design of the new long-scale electrodynamic wattmeters and varmeters of the iron-cored type much thought was given to improved mechanical features as well as to improved performance. In this respect consideration was given to ease of assembly of parts that would greatly facilitate maintenance and service in the field, to more pleasing appearance both inside and outside the instrument, and to better electrical and magnetic characteristics.

The major feature of the redesigned electrodynamic instrument is a unique field coil and laminated-field structure. Figure 10 shows this assembly in detail. The laminations are of a 1-piece construction punched from a new silicon strip steel which permits high flux density and exhibits superior hysteresis characteristics. Care was taken to locate the mounting holes so that losses caused by the mounting rivets would not lessen the efficiency of the magnetic circuit. The laminations are cemented together with a solventless varnish under heat and pressure. This results in a rigid stack of adequately insulated laminations held together without the use of rivets. The only rivets used are the mounting rivets which hold the cemented stack to the support plate as shown in Figure 10. In addition, the field coil after being wound and baked in this new varnish is cast securely to the lamination stack.

The advantages of this method of construction are obvious. Because the solventless varnish is a good heat conductor, the casting of the coil to the laminations permits more efficient heat dissipation and a greater overload rating. Mechanically the cast coil eliminates the use of clips for holding the coil in position and the mold finish presents a pleasing appearance.

Another feature of the mechanical design that will aid the servicing of these instruments greatly is the ability to withdraw the moving system without disturbing the field and coil assembly. In order to realize this objective the die-cast frame is designed so that the frame and moving element are inserted into the hook-shaped section of the lamination assembly. Figure 11 shows this draw-out feature to advantage. All that needs to be done to remove the frame and moving system is to unsolder the lead wires to the moving-system spirals, unscrew the three frame screws, and move the zero regulator until it is restricted by the front jewel support. This removal can be accomplished also with the instrument mounted on a switchboard panel without disconnecting any leads to the base terminals. The draw-out feature has been applied successfully to all instruments that measure single- and polyphase watts and vars.

The moving system and frame assembly are equipped with removable pivots and spring-supported jewels. The pivots are press-fitted into threaded bushings that are screwed into the armature shaft. This permits easy replacement of the pivots if required.

Previous designs always have used external card resistances mounted on the base of the instrument. In the redesign the 120-volt and lower ratings have resistances mounted inside the instrument case. This has made it possible to locate the terminals with increased spacing so that connections can be made more easily and the voltage breakdown value between terminals increased.

The unit lamination and field coil assembly previously described has resulted in a more efficient magnetic circuit. Because of this increased efficiency it has been possible to decrease the field-coil ampere turns and yet obtain a higher torque than that of the previous design. Operating characteristics have been improved thereby, as the ratio of torque-to-weight of the moving system has been increased materially, and the volt-ampere burden of the field coil lowered. Figure 12 gives comparative curves of the field ampere turns versus the torque of the improved and the previous design of electrodynamic system. It can be seen that the field density of the curve A is well be-

Figure 10. Field coil and lamination assembly for wattmeters and varmeters

low the saturation value for normal operating ranges. This fact, coupled with better heat dissipation in the cast field coil, has permitted a larger overload rating without destroying the linearity of the dynamic-torque characteristic.

As is well known in instrument design, the use of iron in the magnetic circuit causes the current in the potential coil to lag slightly behind the applied voltage. Because iron losses more than cancel this effect, compensation is necessary if the instrument is to read correctly on lagging power factor. This is done by shunting the moving coil and a portion of the series resistance with capacitance until such compensation is attained. No attempt will be made in this paper to discuss the theory of this compensation, as it has been covered adequately in another paper.[2]

Inherent in all iron-clad electrodynamic systems is a small error caused by voltage variation. This may be described as a error caused by the solenoid effect between the potential coil and the core embraced by the coil. Excitation of the potential coil alone results in an upscale torque that tends to move the coil in the direction of maximum flux linkage. The more efficient the magnetic circuit becomes, the more pronounced is this "creep" effect. Because of an increased potential flux of the moving coil at a higher voltage, the indication will be slightly high unless this solenoid effect is compensated.

Voltage error can be reduced substantially

1. By designing the moving system to operate with a minimum potential flux.
2. By adequate compensation.

This compensation takes the form of a coil of suitable turns wound on the central core section and connected in series with the moving coil to produce a flux that opposes the extraneous potential flux causing upscale torque. Therefore, when such an upscale torque increases because of increased voltage, the opposing compensating torque likewise increases for the same reason. This substantially eliminates the voltage-creep effect. Figure 13 is a schematic diagram showing the connections for both power-factor and voltage-creep compensation. This method of compensation has been applied successfully to each element of polyphase wattmeters and varmeters.

Power-Factor Meters

Power-factor meters designed for this line of long-scale instruments operate on the principle of the rotating magnetic vane. The two vanes projecting in opposite directions from the shaft are coupled magnetically by a sleeve of nickel-iron alloy. This is surrounded by a stationary current coil which polarizes the vanes, and the coil and vane assembly is mounted inside a motor-type stator with a polyphase winding.

The ideal power-factor meter will indicate correctly the power factor of the circuit regardless of the amount of current flowing. For various reasons, however, this seldom is achieved in commercial instruments. In the conventional 90-degree type, current is led to the moving coil by means of conducting spirals that exert a constant torque proportional to deflection. As the current in the circuit

Figure 11. Wattmeter mechanism with frame and moving system removed

Figure 12. Curves of field ampere turns versus instrument torque

Figure 13. Schematic diagram of connections for power-factor and voltage-creep compensation

Figure 14. Improved power-factor mechanism showing new vane configuration

decreases, this torque becomes a greater percentage of the total torque and thus influences the indication.

In the rotating-vane power-factor meter there are no conducting spirals, so this source of error is eliminated. There are other effects, however, which tend to produce current errors. Most uncompensated instruments have an error of approximately 0.04 to 0.05 power factor between 1- and 5-ampere calibration values. The sources of these errors were analyzed very carefully and most of these effects were found to be of a minor nature. The major extraneous torque might be described as a hysteresis-motor action tending to cause the moving vanes to rotate with potential alone applied. Although this torque has been reduced to a minimum by the use of well-annealed nickel-iron alloys, it was still appreciable. The hysteretic torque has been measured and compared very carefully with the total instrument torque at one and five amperes respectively. Calculations showed errors approximately of the magnitude of the current errors determined experimentally.

The method of compensating for this hysteretic drag in the new instrument consists of modifying the shape of the rotating vanes and changing the stator ampere-turns. Figure 14 shows the approximate shape of the new moving vanes with their relative position inside the current coil and polyphase stator.

These new vanes saturate at a lower value of current flux so that the torque curve from one to five amperes is much flatter than in the previous design and is almost constant from two to five amperes (see Figure 15). Thus the effect of the hysteretic drag is approximately the same over the current range and is eliminated largely in calibration.

It is apparent that a shift in angular flux position also occurs because of this saturation, because it is possible to overcompensate the instrument and produce errors in the opposite direction. The stator ampere-turns, therefore, have been selected to give a hysteretic torque that results in small errors equal in clockwise and counterclockwise directions.

Figure 16 shows how effectively the new system has reduced these current errors. An instrument of the previous design which had a maximum difference of 4.5 per cent between 1- and 5-ampere readings had its moving vanes replaced with the new style vanes and its stator currents corrected to the new value. It will be seen that the error was reduced to slightly over 2 per cent. By calibrating the instruments at some intermediate value, such as 2.5 amperes, this error can be split so that the total deviation from the correct value is approximately 1 per cent. Although Figure 15 indicates a slight loss of torque at rated current, this is compensated for by the decrease in moving-element weight so that the same torque-to-weight ratio is maintained. It also will be noted that the torque at low current values is increased so that the over-all performance of the instrument is improved materially. The operating range also is extended to lower current values before becoming too sluggish for accurate indication.

Figure 16. Current-error curves of power-factor meter

Synchroscopes

The synchroscope has essentially the same physical construction as the power-factor meter. It uses the same rotating-vane system, but the polarizing coil is wound for potential instead of current and is directly connected across the line of the running machine. Most synchroscopes are designed for single-phase operation. Hence it is necessary to provide a phase-splitting network in the stator circuit. This network is built into the instrument case in the new design, which offers distinct advantages over the conventional external-impedor type. To make this possible, inductive reactances were replaced by capacitors and combined with resistances in such a manner that quadrature-phase relation and balanced field currents are maintained. Figure 17 is a schematic diagram of the new stator circuit with a corresponding vector diagram. To obtain a lagging current I_2 in stator coil 2 having the same magnitude but 90 degrees out of phase with I_1, it is necessary to place a capacitance in circuit 2. This causes current I_2 to lead voltage V, but lagging is obtained by reversing the connections to stator coil 2. For testing and calibrating purposes some means of adjustment is necessary. This is pro-

vided by the adjustable resistance R_2. The capacitor C_1 serves to insure the proper phase angle as well as magnitude shift of the current I_1 in stator coil 1 when R_2 is adjusted in test. This resistance adjustment provides a simple and very convenient means of control that is superior to the inductive-reactance adjustment used on previous designs.

By eliminating the external impedor, panel-mounting space has been reduced and the external wiring to the instrument has been simplified. The number of instrument terminals has been reduced to three. Figure 18 shows the external connections to the new design of self-contained synchroscope.

Conclusion

The development of a complete line of long-scale instruments has proved to be a considerable advancement in the field of electrical measurements. In the newly designed instruments all of the desirable features of the initial design have been maintained. Most of the previous limitations have been removed by mechanical improvements that have resulted in greater accessibility and, at the same time, improvements in scale distribution, permanency of calibration under abnormal conditions, and other performance characteristics. Thus these instruments should find even wider fields of usefulness and, in many cases, completely supplant conventional short-scale types.

No Discussion

Measurement of High Q Cavities at 10,000 Megacycles

R. W. LANGE
NONMEMBER AIEE

Synopsis: Known methods of measuring Q in high Q resonant cavities, together with their accuracies and sources of error are discussed. For relatively low values of Q and of frequency, it is shown that band width methods are more accurate than decrement methods. For values of Q above 30,000 at frequencies above 3,000 megacycles the reverse is true. The significant feature of the present method, the wide range heterodyne decrement method, is that the accuracy is improved by observing the decay over a relatively long interval of time. An absolute accuracy of plus or minus three per cent and a relative accuracy of plus or minus two per cent are achieved. Design features and performance are discussed and constructional details are presented.

THE quality factor of selectivity, Q, is applicable to any form of vibratory or oscillatory system. The defining equation is

$$Q = 2\pi \frac{\text{total energy stored in system}}{\text{energy dissipated per cycle}}$$

The present discussion will be limited to electric systems. When the elements are lumped or when the system may be replaced by lumped constants the equation is simplified. For the simple series resonant circuit the expression becomes

$$Q = \frac{X}{R}$$

where

X = reactance of either the coil or capacitor
R = total series resistance

In any simple resonant system energized by a single frequency the phase shift becomes 45 degrees and the displacement is reduced to 0.707 of its maximum value at two frequencies nearly symmetrical about the resonant frequency and separated by the amount

$$\Delta f = \frac{f}{Q}$$

where

f = resonant frequency

This equation has been used to define the Q of certain complex systems.

The working Q of a system differs from the theoretical unloaded Q by a loading factor controlled by the associated devices. All methods measure the loaded (working) Q. For fixed couplings to electric systems under measurement, the loaded Q depends on the standing wave ratio of the coupled (or connecting) circuits as well as on their nominal impedances. In the specific case of a resonant cavity with input and output couplings fixed by design, the loading depends on the voltage and current relationships existing in the input and output transducers. It is important that these impedances be controlled for all methods of measurement of Q outlined here.

Paper 47-23, recommended by the AIEE committee on instruments and measurements for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 13, 1946; made available for printing December 19, 1946.

R. W. LANGE is with Bell Telephone Laboratories, Inc., New York, N. Y.

The author wishes to express his thanks to Doctor W. A. Edson, J. P. Kinzer, and I. G. Wilson of Bell Telephone Laboratories for their suggestions and assistance throughout the original design and final completion of this project, as well as the valuable laboratory assistance of Miss M. J. Kilroy.

Band Width Method

Basic Principle

The frequency corresponding to maximum transmission is measured together with the transmission loss. The two frequencies corresponding to a transmission loss three decibels greater are sufficient to give the selectivity from the general equation

$$Q = \frac{f}{\Delta f} \tag{1}$$

Practical Applications

The method is applicable to all forms of four terminal electric networks. It is therefore directly applicable to cavity resonators having two loops or other coupling devices. It is not applied readily to cavities having a single coupling device. The loss usually is determined by means of a heterodyne transmission measuring set. In this way an attenuator operating at the intermediate frequency and having a relatively accurate calibration may be employed. As a difference in frequency is required, each frequency must be known accurately, or, the difference can be measured directly.

For measurement of resonant cavities it is impossible to secure the signal frequency by beating a fixed centimeter oscillator with a calibrated variable frequency signal generator in the 50-megacycle region or lower. This greatly simplifies the problem of determining the frequency difference.[1]

Alternatively a reflex klystron type of centimeter oscillator may be frequency modulated to furnish the pass band picture of the resonant cavity. The frequency swing can be determined by a frequency modulation receiver augmented by a selective amplifier tuned to the klystron modulating frequency.

Accuracy

Consider a case with a value of Q of 30,000 and a midband frequency f of 3,000 megacycles. Then

$$\Delta f = \frac{3{,}000}{30{,}000} = 0.1 \text{ megacycle}$$

$f_2 = 3{,}000.05$ megacycles
$f_1 = 2{,}999.95$ megacycles

If it is necessary to measure Q to plus or minus ten per cent then, allowing all the error in the denominator, Δf must be measured to plus or minus ten per cent. If the frequencies are measured directly then each must be known to plus or minus 5 kc.

Actually the loss cannot be determined exactly at either midband or 3-decibel points. If an error of plus or minus 0.1 decibel is allowed for each of these measurements the uncertainty of the answer is increased by about plus or minus six per cent. To measure absolute values of Q by this method to an accuracy better than plus or minus five per cent requires extreme care and considerable skill in manipulation.

In systems where the Q is low the frequency difference may be determined with negligible error, and the accuracy is limited only by the loss measurements.

Input Standing Wave Ratio Method

Basic Principle

The standing wave ratio of the input device is measured at three or more frequencies in the region of the resonance. The Q of the cavity then is computed from the variation of the standing wave ratio with respect to frequency.

Practical Applications

The method is applicable to any form of cavity having one or more coupling devices. The quantities to be measured are the same as in the band width method—frequency and voltage level. Accordingly the same general techniques are applicable. Because the standing wave ratio is usually high a heterodyne method is desirable.

Accuracy

The same errors appear here as in the band width method. A small difference between two relatively high frequencies must be determined, and voltage levels must be measured with sufficient accuracy to determine the difference between several comparable standing wave ratios. The over-all accuracy is not likely to be better than that of the band width method and easily may be poorer. The principal advantage is that a single coupling device is sufficient to permit a measurement.

Figure 1. Video decrement method for measuring the Q of resonant cavities

(a). Block diagram of the method
(b). Complete video signal (showing build-up and decay of ultrahigh frequency energy in resonant cavity)
(c). Video decay signal (used in measurement of Q)

Video Decrement Method

Basic Principle

In this method, shown in a block schematic drawing in Figure 1(*a*), the build-up and decay of ultrahigh frequency enery within the resonant cavity is rectified by a crystal detector producing a video signal which is amplified and observed as the vertical deflection on an oscilloscope having a linear time axis. A measurement is made on the oscilloscope of the rate of decay in terms of amplitude in decibels and time in microseconds. The Q may be computed from these quantities and a calibration of the curvature of the crystal characteristic by using the formula

$$Q = 27.3(f)(\Delta t/\Delta db) \qquad (2)$$

where

f = frequency in cycles per second
Δdb = decrement in decibels observed in the time increment Δt seconds

Practical Application

The pulsed ultrahigh frequency signal is applied to the cavity through an input coupling and is delivered to the crystal through an output coupling connection. This method provides a convenient and fairly accurate arrangement for observing decrements. It is quite satisfactory for observing moderately small changes from reference decrements for development work. The signal source should be adequately decoupled from the cavity to prevent pulling. The crystal is operated well under the overload point and sufficiently above the noise level to permit examination of the main mode of the cavity. The video system following the crystal need never be overloaded.

In general, the crystal video output is some exponential function of the ultrahigh frequency input. If absolute measurements are to be made, it is necessary to determine this relationship at the operating signal levels.

The complete video signal observed on the oscilloscope is shown in Figure 1(*b*). The signal oscillator is pulsed on at point A and continues to oscillate to point B, at which time it is pulsed off. The energy within the resonator builds up in the interval A to B and starts to decay at B.

In actual measurement the sweep time axis is delayed or phased with respect to the signal oscillator pulse so the full screen may be utilized in measuring the decay portion B to C.

The initial observation, point B in Figure 1(*c*), is made at or slightly after the instant the signal oscillators stop pulsing. The choice is dependent upon the sharpness with which the signal oscillator is pulsed off. The second observa-

tion point C is made at a point before the decay curve becomes asymptotic to the horizontal reference line. Point C usually is selected three decibels below point B. The Q is computed by equation 2 where the value of db is measured on the vertical calibrated scale and time along the calibrated linear sweep axis.

The method is not directly applicable to cavities having only one coupling device.

Accuracy

For conditions which have been found most satisfactory in the laboratory the error attributed to reading the oscilloscope is plus or minus seven per cent. This can be considered the accuracy of relative measurements of Q.

For an absolute measure of Q the errors involved in calibrating and using the crystal must be added to the foregoing factors. No attempt has been made to evaluate these errors; however it is reasonable to state that this method lacks the accuracy ultimately desired. Error contributed by uncertainty in observation of the frequency is negligible.

No decrement method is applicable to the measurement of low Q systems because of the extremely short time intervals involved and the correspondingly great band widths required.

Heterodyne Decrement Method

Basic Principle

A decrement method is employed to avoid precise measurements of frequency difference. The circuit is shown in block schematic form in Figure 2.

The pulse from the ultrahigh frequency oscillator is applied as a signal to the cavity under test. The decay of energy within the cavity after the signal pulse has ceased is observed through a heterodyne detector circuit ending in an oscilloscope. Two distinct points are observed and compared on the decrement curve. Values of level in decibels and of time result from this comparison and the Q of the cavity is computed from equation 2.

The method differs from the previous one in three important respects.

1. The crystal is energized by a beating oscillator as well as by the signal from the resonant cavity under test. The principal advantage is that the crystal now serves as a linear modulator eliminating the question of crystal exponent.

2. The beating oscillator is pulsed off or shifted in frequency during the main pulse to avoid overload in the intermediate frequency and video systems. Moreover by pulsing the beating oscillator it is practical to employ the method with single-coupling as well as 2-coupling cavities.

3. The range of decrement is increased to approximately 20 decibels so observations of loss and time increments give improved accuracy of Q determination.

The complete build-up and decay of the pulse with the beat oscillator operated continuous wave is shown in Figure 3(a). The signal oscillator pulses on at A and the energy within the cavity builds up from A to B where the signal oscillator is pulsed off. The decay of energy is shown as B to C.

With an ideal beat oscillator pulsed on at time t_0 the decay curve would appear as shown in Figure 3(b) with a sharp increase to full height at t_0. Actually there is a finite build-up time for the beat oscillator during which the energy within the cavity continues to decrease, so that the resultant curve has a gradual build-up from t_0 to t_1 as shown in Figure 3(c) and in Figure 4. (Abnormal intensities were used to facilitate photography.)

The fixed timing spot shown as t_2 in Figure 3(d) appears as an end to the decay trace. This end is sharp and permits an exact alignment of the height of the figure at t_2 with the horizontal reference line on the oscilloscope as shown in Figure 4. (Abnormal intensities were used to facilitate photography.)

The intersection of the fixed timing spot on the decay curve with a reference line on the oscilloscope is adjusted either by changing the precision delay, or the intermediate frequency attenuator, or, within limits, the video gain of the Y axis of the scope. The base line of the image is aligned with the horizontal reference line by vertical positioning on the oscilloscope. The initial observation is made with the maximum loss setting of the intermediate frequency attenuator and the precision delay circuit adjusted to an arbitrary reference point near the minimum delay. The figure is adjusted to a standard height at t_2 by the video gain control. The delay time is read from the dial of the precision delay circuit.

For the second observation at a point later in the decrement curve as shown in Figure 3(e) the intermediate frequency attenuation is reduced and the delay circuit adjusted to provide the same standard figure height at t_2 shown for t_2 in Figure 3(d). The delay time is read from the dial of the precision delay circuit. From the foregoing procedure the change

Figure 2. Heterodyne decrement method for measuring the Q of resonant cavities

Figure 3. Build-up and decay patterns observed in heterodyne decrement method

in attenuation in decibels and the corresponding time are obtained, and the Q computed from equation 2.

Practical Applications

The present set is used with cavities having 2-coupling devices but it has been modified to operate with cavities having a single-coupling device without serious loss of performance.

The free-running multivibrator shown in Figure 6 sets the repetition rate and pulse length of the signal oscillator and triggers the precision delay circuit. The multivibrator furnishes a flat top pulse with a rise and more particularly a decay in 0.3 microsecond or less.

The signal oscillator uses a velocity variation focused beam oscillator tube in an adjustable cavity. It is pulsed on by a voltage applied to the accelerating anode. This pulse is furnished by a video driver amplifier, integral with the oscillator unit, which amplifies and clips the pulse supplied by the multivibrator. The pulse wave to the accelerator decays in less than 0.1 microsecond.

Excellent frequency and amplitude stability of the signal oscillator is required during the short intervals of measurement (one minute or less) for which the oscillator must remain tuned to the resonant cavity. In the set which was constructed, precautions were taken to obtain a short time frequency stability considerably better than 0.1 megacycle. All voltages, except heater supply, were furnished by well-regulated and filtered power supplies. The heater was operated on rectified alternating current, heavily filtered, to avoid modulation from the heater circuit. All supplies were operated from a voltage regulating transformer. Finally, frequency drift caused by changes in the ambient temperature were eliminated by a draft shield.

Figure 4. Photograph of oscilloscope trace showing complete decay pattern observed in heterodyne decrement method

Figure 5. Photograph of oscilloscope trace showing decay pattern blanked by timing pulse

Amplitude modulation was controlled by the foregoing method and by applying a flat top pulse to the accelerating anode of the signal oscillator. The signal frequency is delivered to the input of the resonant cavity through wave guide or coaxial connections and the output is fed through suitable connections to the converter. It is desirable that the impedance offered to the resonant cavity be that which exists when the cavity is working normally.

The linear converter circuit employs a crystal of the *JAN 1N23B* type in a wave guide mounting. The beat oscillator delivers sufficient power to the converter through a probe inserted in the wave guide or by a directional coupler to operate the crystal at optimum signal-to-noise ratio. The low level signal from the resonant cavity is applied directly to the crystal converter through the minimum loss consistent with obtaining the desired impedance at the output of the resonant cavity. It is a distinct help to adjust the particular crystal in the converter to obtain a low voltage standing wave ratio.

The intermediate frequency output of the crystal is fed directly to a low gain preintermediate frequency amplifier integral with the converter unit and designed to give a good signal-to-noise ratio. The combined unit is a modification of an airborne radar component. The output of the last stage is matched to work directly into a variable intermediate frequency attenuator. The load carrying capacity is adequate to insure constant gain for all signal levels encountered.

The main body of the intermediate frequency amplifier and detector follows the variable intermediate frequency attenuator. The disposition of the gain from the output of the attenuator to the oscilloscope is not critical for the signal level remains unchanged in this portion of the circuit. It is desirable that a good signal-to-noise ratio be obtained in the intermediate frequency amplifier.

The complete intermediate frequency system should provide a moderate band width of two to five megacycles at the 3-decibel points. To ease the requirement on stability of the beat oscillator the mid-band should be flat to a few hundredths of a decibel. A flat band width of 0.5 to 1 megacycle is sufficient.

The detector following the intermediate frequency amplifier normally is back-

Figure 6. Circuit of multivibrator establishing repetition rate of signal oscillator

biased and driven by the signal into a square-law region to increase the differential sensitivity.

The beat oscillator is a velocity-variation reflection-type oscillator tube which is pulsed on by a voltage applied to the repeller. This pulse is furnished by a pulse amplifier, associated with the beat oscillator, which amplifies and clips the pulse supplied by the beat oscillator pulser.

As an alternative, the beat oscillator may be frequency modulated to the extent of some ten megacycles by reducing the peak value of the pulse applied to the repeller and making a compensating change in the d-c repeller voltage. The frequency of the beat oscillator is fixed during the interval of measurement as that which produces the required intermediate frequency signal. The frequency modulation shifts the beat oscillator from its off frequency to its on frequency position and maintains that frequency throughout the measurement interval. The operation of the tube in this manner in general reduces the transient intermediate frequency component generated during the build-up of oscillation when the tube is pulsed on. This transient upon conversion is the equivalent of a false signal at the input of the intermediate amplifier.

With either type of modulation of the beat oscillator it is necessary that the frequency remain sufficiently constant to keep the intermediate frequency output of the converter well within the very flat intermediate frequency band. This is accomplished by regulation of the oscillator voltage and the application of a flat top pulse. Further, it is necessary to maintain a constant ambient temperature to eliminate frequency changes. The tube is protected by double thermal shields.

The delay circuit is a monovibrator circuit triggered by the leading edge of the pulse from the precision delay circuit. The output pulse of the delay circuit furnishes a timing spot which is the reference mark on the decay curve appearing on the oscilloscope. Actually the pulse is used to blank the oscilloscope trace providing a sharp end mark on the decrement curve. It is important that the pulse be free of jitter as to time and shape. As shown in Figure 2, it is the sharp transition from positive to a negative voltage that is utilized. Thus the oscilloscope trace is brightened immediately before it is blanked.

For a specific test condition the time delay furnished by the circuit is fixed; however, for general testing it is convenient to have this delay under manual control. The delay may be varied under control of a potentiometer from a minimum of three-fourths to a maximum of five microseconds.

The precision delay circuit, shown in Figure 7, is a monovibrator circuit triggered by the trailing edge of the pulse applied to the signal oscillator. It provides a sharp output pulse accurately delayed from the triggering pulse. The time delay, under manual control of the variable air capacitor C_1, is continuously variable and calibrated. For testing in the 10,000-megacycle range a delay of 1 to 12 microseconds was used.

A commercial 5-inch oscilloscope has been modified for a sweep of five to ten microseconds and for double intensity modulation. Both the normal unblanking during the sweep trace and the reference pulse are applied to the intensity grid of the cathode ray tube.

A special nonglare hood is attached to the oscilloscope to facilitate daylight viewing of the trace. Two pairs of horizontal lines $1^1/_2$ inches apart are scribed on the front and rear surface of an edge-lighted plexiglass plate providing reference lines free of parallax.

Extension of Frequency

By changing the oscillators and converter the set has been applied to the 3,000- and 24,000-megacycle frequency bands. A minor change of components in the precision delay circuit permits adjustment of time delay to the particular frequency and range of Q to be measured.

Sets operating at these frequencies have been constructed and operated over considerable periods.

Accuracy of Measurements

These figures apply to a practical application at about 10,000 megacycles for a range of Q from 45,000 to 150,000.

Measurement of Time. The maximum error in determining the time at one dial setting of the precision delay circuit is ± 0.03 microsecond so that the maximum error of two time measurements in determining Q is $\pm$ 0.06 microsecond.

The least time interval expected is 3.5 microseconds corresponding to a 20-decibel change in the decrement curve of a relatively poor cavity having a Q of 45,000. The error in time measurement is $\pm 0.06/3.5 = \pm$ 1.7 per cent. The maximum time measurement expected is 8.1 microseconds for a Q of 100,000. The error is $\pm 0.06/8.1 = \pm 0.7$ per cent.

Observational Error of the Oscilloscope.

Figure 7. Precision delay circuit used for timing in heterodyne decrement method

R_1, R_2 = precision wire-wound noninductive resistors
C_1 = precision variable air capacitor

a change of one decibel at the intermediate frequency produces a change in video deflection observed on the scope of one-half inch. With this differential sensitivity the spot timing on the decrement curve can be adjusted to the reference line to an accuracy of ±0.05 decibel which is ±0.25 per cent of the 20-decibel change. The adjustment of the base line of the figure to the reference line cancels because consecutive measurements are made with the same adjustment. It is important to note that the oscilloscope is used as a comparison tool rather than for direct measurements which reduces observational errors.

Frequency Error. The error in frequency determination is a maximum of ±0.05 per cent.

Change in Attenuation. The error in the change in attenuation is within ±0.25 decibel which is ±1.25 per cent.

Over-all Accuracy

The errors for absolute and relative measurements are given in Table I.

Conclusion

Sets for the measurement of high Q resonant cavities at about 3,000 and 10,000 megacycles have been built and satisfactorily operated in both the laboratory and in the factory for production testing. A set operating at 24,000 megacycles has been used in the laboratory.

A Polyphase Thermal Ampere-Demand Meter

A. J. PETZINGER
MEMBER AIEE

Synopsis: Reduction of the initial and maintenance costs of the metering equipment required for the measurement of kilovolt-ampere demand has been an objective of the metering industry for many years. The development of a method of measuring polyphase ampere demand has made possible a simple and compact meter which registers kilowatt-hours and indicates maximum ampere demand. A good approximation of true kilovolt-amperes demand is then obtained by multiplying this maximum ampere demand by an assumed base voltage.

KILOVOLT-AMPERE DEMAND long has been one of the quantities which often is involved in billing a consumer for electric service. Undoubtedly one of the factors which has discouraged more widespread measurement of kilovolt-ampere demand has been the fact that the initial cost and maintenance of the metering equipment has been relatively expensive. Recording meters and indicating demand meters are available which measure true kilovolt-ampere demand, and their use is justifiable on large loads. On smaller loads, however, their use may be uneconomical.

For such applications a less expensive form of metering is highly desirable. It is natural that the possibility of using thermal meters should be investigated, as thermal meters require a minimum of maintenance.

One answer to the problem is the thermal kilovolt-ampere demand meter employing the displaced voltage principle. Taps are provided for metering at 100 per cent, 87 per cent, 71 per cent, and 50 per cent power factor. Accuracy is good if the operating power factor is reasonably close to the tap on which the meter is set. Besides the bimetal springs and the associated heaters and boxes, the required parts are two current transformers, two potential transformers, two phase shifting transformers, and facilities for tap changing. (In one form the potential and phase shifting transformers may be combined. For certain capacities the current transformers may be omitted on 3-wire circuits.)

There is, however, another approach to the problem which obtains kilovolt-ampere demand through the indication of a thermal ammeter. This paper deals with such a meter.

Single-Phase Meter

As electric service is supplied at various voltages and from various circuits, ampere demand as such is practically meaningless, unless the voltage is specified. For a given circuit and voltage ampere demand can be converted to kilovolt-ampere demand to provide a common basis. The scale of the meter shown in Figure 1 is, therefore, marked in kilovolt-ampere demand based on the normal circuit voltage.

On 2-wire circuits, the heaters are placed directly in series with the current winding of the watt-hour meter electromagnet.

On 3-wire meters, the use of a 3-wire transformer is necessary, as the heaters must be supplied with a single current which is equivalent to the currents in the two lines.

A simple example will illustrate this. If one heater were used in each line (Figure 2), the total heat generated would be

$$I_1^2R+I_2^2R$$

If $E_{10}=E_{20}=120$ and $E_{12}=240$, the kilovolt-ampere should be the same for $I_1=I_2=10$, $I_3=0$ as for $I_1=I_3=5$, and $I_2=0$, that is, 1.2 kva.

With $R=0.012$, the first case would give heat $=(10)^2\times0.012=1.2$ watts, whereas the second would give $(5)^2\times0.012+(5)^2\times0.012=0.6$ watts. However, if the currents are combined by a 3-wire transformer, each on a 1/1 basis, for example, the result in either event would be a secondary current of ten amperes (Figure 3).

If the voltages are balanced and of nominal value, the meter will read the correct value of kilovolt-amperes. The vector kilovolt-amperes also will be correct, if the power factors of the currents differ, as the transformer secondary current is proportional to the vector sum of the currents I_1 and $-I_3$. The minus sign indicates that the I_3 current is reversed or shifted by 180 degrees, the same angle as that between E_{01} and E_{02}.

Theory of Operation—Polyphase Meters

General

When an attempt is made to use the same principles on polyphase circuits, the problem immediately becomes more complicated. Even three ammeters on a 3-phase circuit do not provide the correct readings unless the load is balanced both as to magnitude and phase angle.

For example, suppose ammeters are placed in each line of a 240-volt 3-phase, 3-wire circuit. A 10-ampere load between lines causes two ammeters to read $10^2R=100R$, or a total or 2.4 for an arbitrary value of $R=0.012$. If the load is ten amperes on each line, the reading will be $3(10^2\times0.012)=3.6$. In the first case, the reading is the same as the kilovolt-amperes; in the second, the reading is 3.6 while the kilovolt-amperes equal 4.16. In this ex-

Paper 47-24, recommended by the AIEE committee on instruments and measurements for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 12, 1946; made available for printing December 30, 1946.

A. J. Petzinger is with the meter engineering department, Westinghouse Electric Corporation, Newark, N. J.

Figure 1. A single-phase thermal ampere-demand watt-hour meter with kilovolt-ampere scale

ample, if the meter were adjusted to read kilovolt-amperes correctly on balanced load, it obviously would be incorrect on other loads.

As another example, a network circuit (two phases and neutral of a 3-phase, 4-wire Y circuit) is particularly subject to unbalanced loads and the totalized readings of two meters, one in each phase, give various values depending on the division of load between the phases.

Another consideration is the assumption of a coincident maximum demand on the several meters. This is not necessarily the case. A further objection to the use of a thermal ammeter in each phase is the complication and cost incident to the purchase, installation, maintenance, reading, and billing of such a combination.

If now a single meter is to be used, it is obvious that some method must be found of properly shifting the individual currents by the required amounts and obtaining the vector sum before the result is applied to a thermal unit. It is evident that no combination of the sums or differences of the currents in a polyphase circuit will accomplish this.

Meter for the 3-Phase 4-Wire Delta Circuit

The desired result, however, can be obtained by another method. First it may be well to define the kilovolt-amperes of any circuit. The kilovolt-amperes or vector power is defined as the square root of the sum of the squares of the total active power and the total reactive power. The common methods of measuring kilovolt-ampere conform to this definition.

The basis of the method of phase shifting is the fact that a given current flowing through a resistance will produce a voltage drop in phase with the current, whereas the same current flowing through the primary winding of a mutual inductance will produce an induced voltage in the secondary, which is 90 degrees out of phase with the current. Figure 4 shows the basic circuit for use on a 3-phase 4-wire delta system.

If R_H is open-circuited, the voltage E across the open section is

$$j\omega MI_1 - j\omega MI_3 + I_3R$$

If

$$R = \sqrt{3}\omega M$$

Then

$$E = \omega M(jI_1 - jI_3 + \sqrt{3}I_3)$$

Though it is not an operating condition, a load consisting of resistances between lines and neutral with all line currents of equal magnitude is helpful in visualizing the operation of the circuit. In such a case the kilowatts equal the kilovolt-amperes. Figure 5 shows the vectors for this circuit with the load described. If the single-phase 3-wire portion of the circuit is considered first, it is seen that the voltage derived from current in line 1 is rotated 90 degrees counterclockwise by the mutual inductance, whereas that derived from the current in line 2 is rotated 90 degrees clockwise, with reference to the respective currents. These two voltages are, therefore, in phase and add just as the currents in the case of the single-phase 3-wire ammeter.

The current in line 3 has been assumed to be of the same magnitude as the other two lines, but the voltage, E_{30}, is $\sqrt{3}$ times as large as E_{10} or E_{20}. The voltage derived from line current 3 therefore should be $\sqrt{3}$ times as large as each of the others, and this voltage also should be in phase with the others. A resistance drop of the required magnitude fulfills these conditions ($R = \sqrt{3}\omega M$).

It is apparent that increasing the magnitude of the current in any line will increase the resultant voltage by the proper amount. Also, if any line of the currents has a reactive component, this reactive component will produce a component in the resultant output voltage which is 90 degrees out of phase with the active component of the voltage. The resultant voltage therefore, will be a measure of the circuit kilovolt-amperes if the system voltages are assumed to be balanced and of normal magnitude.

The voltage E is the voltage across R_H assumed as an open circuit. If this open

Figure 2. Ammeter for 3-wire service with heater in each leg

Figure 4. Basic circuit for a polyphase ammeter on 3-phase 4-wire delta service

Figure 5. Vector diagram for Figure 4 with each phase resistance loaded to neutral

circuit is closed, the current circulating in the loop will be

$$I_H = E/\sqrt{(R+R_H)^2+\omega^2L^2}$$

where L is the self-inductance of the secondary winding of the mutual inductance, and R_H is the resistance of the heaters of a thermal ammeter unit. The current is, therefore, proportional to the vector kilovolt-amperes of the polyphase circuit at a given voltage, as the loop impedance is constant.

Operation of 3-Phase 4-Wire Delta Meter on Different Loads

Figure 6 shows the vector diagram for various other types of single-phase and polyphase loads, all of which are correctly metered.

It will be noted that the resultant voltage of all kilowatt loads lies along the E_{30} vector, while that of the lagging var load lies along a vector lagging the E_{30} vector by 90 degrees. The vector kilovolt-ampere is, therefore, correct, regardless of what the phase angle of the various loads may be.

In Figure 6 the voltage referred to is the voltage across R_H in Figure 4, if it is assumed to be an open circuit. In Figure 6 the conditions are shown for a balanced polyphase load. In this case $j\omega MI_1$ leads I_1 by 90 degrees, $-j\omega MI_2$ lags I_2 by 90 degrees, and I_3R is in phase with I_3. As shown by the voltage vector diagrams, the sum of these terms $=2\sqrt{3}$ for the values assumed, and this is equal to the kilovolt-amperes of the load.

Figure 6 shows the conditions for a single-phase load across lines 1 and 2. In this case the voltages $j\omega MI_1$ and $-j\omega MI_2$ are in phase and add up to two, which again equals the kilovolt-ampere of the load.

Figure 6 shows the conditions for other single-phase loads. In each case the resultant voltage is the sum of a reactance and resistance term of magnitudes 1 and $\sqrt{3}$ respectively, which gives a resultant of two.

Figure 6 shows a combination of a unity power factor load of 1 kw and 50 per cent load factor balanced polyphase load of $\sqrt{3}$ kva. The vector kilovolt-ampere equals 2.4, and the voltage E likewise totals 2.4. In determining the magnitude of E, the two loads may be treated independently to determine the voltage contributed by each. These voltages, however, must be added vectorially to determine E. As mentioned before, the resultant voltage on a unity power factor load is always along the 3–0 direction, whereas that of reactive loads is along the 1–2 direction in Figure 4.

Other Circuits

For 3-phase 3-wire circuits, the same arrangement can be used, as the neutral current was not involved in the 3-phase 4-wire delta meter.

For network service from a 3-phase 4-wire Y circuit, the diagram in Figure 7 applies.

For 3-phase 4-wire Y service, the circuit shown in Figure 8 may be used. In this case a 3-wire transformer, with polarity as shown, is used to achieve the required shift.

The use of transformers permits the circuits to be modified. The circuits actually used in the various services are shown in Figures 9 to 12. The derivation of these circuits is given in Appendix I.

Application of Symmetrical Component Theory

As stated before, it is assumed that the voltage is balanced. This is an assumption that is common to several forms of kilovolt-ampere metering. For example, a true kilovolt-ampere meter measures the vector sum of the kilowatt and kilovar registrations. The kilovar meter usually employs phase shifting transformers to obtain potentials of the desired magnitude

Figure 6. Vector diagram of currents and voltage for various loads on circuit of Figure 4

Figure 7. Polyphase ammeter circuit without transformers for network service

and phase. Whenever phase shifting transformers are used, balanced voltages are assumed, and errors result from unbalanced voltages.

A common form of phase shifting transformer, for example, used on 3-phase 4-wire Y circuits, is shown in Figure 13. E_{DE} is the voltage which should be equal to E_{AN} and should lag it by 90 degrees. The error is actually *twice* the negative sequence voltage plus the zero sequence voltage. (See Appendix II.) Similarly for 3-phase 3-wire circuits, the error is twice the negative sequence voltage.

As the meters described measure the positive sequence current, only the positive sequence volt-amperes are measured. The error due to unbalance is, therefore, equal to the negative sequence (and sometimes the zero sequence) volt-amperes. The unbalance error, therefore, is much less than that of conventional var-hour meters. The error in measuring kilovolt-ampere by this method is thus dependent almost completely on the relative magnitudes of the assumed and actual voltages at the time of maximum demand.

Meter Construction

The foregoing circuits and vector diagrams illustrate the principles involved in metering various circuits. Various modifications are possible and desirable in designing the meters. All the circuits in Figures 4, 7, and 8 show the resistors and mutual inductances at line potential.

It is desirable and convenient, however, to use current transformers. Otherwise, when the value of current is large, the components and their assembly become difficult to handle and control because of the heavy cable size. Also, in a thermal meter, if large conductors are connected to the heaters, the heat in the heaters is drawn away by conduction through the cables. This decreases the efficiency with a correspondingly greater watt loss required for full scale deflection. It will be seen that the resistor R, Figure 6, is connected to heater R_H. As will be shown later, the current in the resistor is not the same for equal loads in different phases. This is illustrated by Figure 14. If the heater and resistor are connected by heavy cable, the heat in the resistor will affect that in the heater because of the excellent conduction between them. If current transformers are used, this tendency can be made insignificant.

The use of the current transformers also makes possible variations of the basic circuit as shown in Appendix I.

Figure 15 shows the meter used for 3-phase 3-wire service. The size of the meter is the same as that of 3-element watt-hour meter. The terminal block and trim are the same as the 2-element meter for the same service. All watt-hour meter parts are essentially the same as those of the corresponding watt-hour meter.

To obtain balance between the phases, either the mutual inductance or the resistance must be adjustable. In the meter shown, the iron-cored mutual inductance is adjustable by means of a sliding keeper shunting its air gap. When the meter is calibrated for proper balance, the simplest way is to check the voltage across a heater by means of a vacuum tube voltmeter while single-phase current is passed through successive phases.

Another advantage of using current transformers is that the components—heaters, resistors, and mutual inductances—for the several circuits can be standardized easily. Also various full-scale capacities are possible by changing current transformer ratios without changing the circuit components or the method of assembling them.

The scale of the meter has a basically squared distribution, as do those of other thermal ammeters. It can be calibrated in amperes, or for a given voltage, in kilovolt-amperes.

Design Considerations

The optimum value of the heater resistance can be determined as outlined in Appendix III.

The curves shown in Figure 14 show

Figure 8. Polyphase ammeter circuit with one transformer for 3-phase 4-wire Y service

Figure 9. Polyphase ammeter circuit with transformers for 3-phase 4-wire Y service

the variation in the heater and resistor watt loss with variable x. It will be seen that the value of the heater resistance need not be held within close limits in order to keep the deflection within the calibrating range of the meter. This is in contrast to the usual thermal ammeter in which deflection is proportional to heater resistance. From the curves it is evident that the meter is not sensitive to heater resistance.

Actually, ambient temperature considerations make it desirable to use a heater resistance somewhat below the optimum value. The mutual inductance does not vary with the temperature, so the resistor and the heater likewise should have zero temperature coefficient. An unheated bimetal spring opposes the heated spring, thus canceling most of the ambient temperature errors in the springs. However, there still remains a tendency for the deflection to fall off with increasing temperature. It is therefore desirable to use heater material with a slightly positive temperature coefficient and to keep the heater resistance below the optimum value. Then, as the temperature rises, the heater resistance increases slightly, which in turn increases the deflection. Conversely, if the bimetal deflection characteristics were positive, the heater resistance should be kept above the optimum value.

When transformers are used, they may employ different ratios in the different phases. For the circuit shown in Figure 12, assume the transformer ratio for phases 1 and 2 is N_1, and the ratio for phase 3 is N_2. Then

$$R = \frac{N_1}{N_2}\sqrt{3}\omega M$$

Also the optimum value of heater resistance becomes

$$R_H = \omega M\sqrt{3\frac{(N_1)^2}{(N_2)^2}+1}$$

While the efficiency may be decreased, if $N_1/N_2 \neq 1$, there may be compensating

advantages in the standardization of components and ease of manufacturing them.

A study of Figure 14, which applies to the 3-phase 4-wire delta circuit of Figures 4 and 12, discloses interesting information. The heat in the resistor at balanced load is a minimum when $R_H/\omega M=2$. This is to be expected, as the heat in the heater is a maximum at this point. It is important, also to note that the heat in the resistor on full-scale balanced load is much less than the heat in the resistor at one-third scale for any possible single-phase load. The reason is that the current circulated in the heater circuit almost completely cancels the current which would flow in the resistor if the heater circuit were opened. Also, the single-phase load which causes the greatest resistor loss is a load across lines 1 and 3 which, normally, is not an operating condition. Near $R_H/\omega M=2$ the heat in the resistor is almost the same for a load across lines 1–2 as across 2–3. Single-phase loads across lines 1–2 or 1–0 and 2–0 are normal operating conditions.

Similar curves can be drawn for other circuits. In each case, it is usually best to design for the minimum loss in the resistor on balanced load.

As might be suspected, there are numerous circuits which may be used to perform the desired phase shifts on a polyphase circuit. For example, a simple interchange of the function of resistance and reactance (multiplying the equations by $-j$), gives circuits which are entirely practical. One criterion of the relative excellence of different circuits is heat loss in the resistor. On a thermal meter the total heat generated must be limited in order to prevent excessive temperature rise, or to permit operation over wide ambient temperature ranges. One method of controlling this factor is to select the most efficient circuit. Another factor of practical importance is the size of the resistor required, which varies directly with the watt loss. The relative heat in the heater and resistor is, therefore, an important design consideration.

Figure 10. Polyphase ammeter circuit with transformers for network service

Testing

The polyphase thermal ampere-demand meter is tested like other thermal meters, with two exceptions:

1. Balance between phases is adjusted most conveniently by checking the voltage across a heater with a vacuum tube voltmeter when a single-phase load is applied. On the meters described, current in phase 1 feeds only the mutual inductance which is adjustable. The other phases are affected only slightly by the adjustment.

Figure 11. Polyphase ammeter circuit with transformers for 3-phase 3-wire service

2. Full-scale calibration should be set on a balanced polyphase load. A single-phase current can be passed through each phase of the meter in series, direct or reversed, but this is not an operating condition, and full-scale current will not produce full-scale deflection. The use of single-phase current is, therefore, undesirable for calibration.

After a standard has been established it is no longer necessary to control the magnitude and balance of the current exactly, as test meters can be calibrated to read the same as the standard.

Application

One feature of any squared scale instrument which must be recognized is that half of full-scale current corresponds to only one-fourth scale deflection, and so forth. In the case of a 45-ampere full-scale meter, the lowest current marked on the dial is 10 amperes. Also, any error which is independent of deflection causes a relatively high percentage error in terms of the full-scale current at low points on the scale, and small percentage errors at high scale values. An error which at a 15-ampere load would represent a 1-ampere error on the scale would represent only a 0.3-ampere error at a 45-ampere load, as the linear distance between successive ampere points is three times as great at 45 amperes as at 15 amperes.

Conclusion

The meter described in this paper should be useful to those who are searching for more economical means of metering kilovolt-ampere demand on loads which, heretofore, have been too small to justify that type of metering. The use of an assumed voltage perhaps will be looked upon with disfavor in certain quarters. However, it is almost certain that the possibility of measuring kilovolt-amperes to a good approximation at relatively low cost will more than offset any disadvantages of this type of meter.

Appendix I

On a 3-phase 4-wire Y circuit (Figure 9), the currents I_1 and I_3 must be shifted by 120 degrees and 240 degrees, respectively, with reference to I_1. If I_1 is assumed to feed a mutual reactance, it can be seen that the required voltage would be

$$E=-j\omega M\left[I_1+I_3\left(-\frac{1}{2}+j\frac{\sqrt{3}}{2}\right)+I_3\left(-\frac{1}{2}-j\frac{\sqrt{3}}{2}\right)\right]$$

When I_3 is added to and subtracted from the quantity in brackets

$$E=-j\omega M\left[I_1+I_3\left(\frac{1}{2}+j\frac{\sqrt{3}}{2}\right)-I_3\left(\frac{1}{2}+j\frac{\sqrt{3}}{2}\right)-I_3\right]$$

$$=-j\omega M\left[(I_1-I_3)+\left(\frac{I_3-I_1}{2}\right)(1+j\sqrt{3})\right]$$

$$=-(I_1-I_3)j\omega M+\left(\frac{(I_3-I_1)}{2}\right)\times(\sqrt{3}\omega M-j\omega M)$$

Figure 12. Polyphase ammeter circuit with transformers for 3-phase 4-wire delta service

Figure 13. Schematic diagram of phase shifting transformer for 3-phase 4-wire Y service

Figure 14. Heat in heater and resistor on various loads for meter of Figure 4 for different ratios of heater resistance to mutual resistance

——— Heat generated in resistor for load giving one-third scale deflection on phase indicated

▬▬▬ Heat generated in resistor for full-scale balanced load

- - - - Heat generated in heater for one-third scale deflection

—·—·— Heat generated in heater for full-scale deflection

Replacing $\sqrt{3}\omega M$ by R yields

$$E=-(I_1-I_2)j\omega M+\left(\frac{(I_2-I_3)}{2}\right)(R-j\omega M)$$

This can be measured by the circuit shown in Figure 9. The turn ratio (primary/secondary) of the transformer in lines 2 and 3 is half that of the transformer in lines 1 and 2.

On 3-wire network service, a similar circuit is shown in Figure 10. The voltage E for this circuit is

$$E=I_1j\omega M-\frac{I_3}{2}(R+j\omega M)$$

where

$$R=\sqrt{3}\omega M$$

or

$$E=j\omega M\left[I_1+I_3\left(-\frac{1}{2}+j\frac{\sqrt{3}}{2}\right)\right]$$

On a 3-phase 3-wire service, the same circuit can be used as for the network service, except that the connections of the transformer in line 3 must be reversed from those of the transformer in line 2 of Figure 10 because of the different phase relation of the voltages.

The connections are shown in Figure 11 where

$$E=I_1j\omega M+\frac{I_3}{2}(R+j\omega M)$$

where

$$R=\sqrt{3}\omega M$$

Figure 15. A polyphase thermal ampere-demand watt-hour meter with kilovolt-ampere scale

Appendix II

See Figure 13. For phase A:

Voltage required $=jE_{NA}$

Voltage obtained $=\frac{\sqrt{3}}{3}(E_{NC}-E_{NB})$

$$\text{Error}=\frac{\sqrt{3}}{3}(E_{NC}-E_{NB})-jE_{NA}$$

$$=\frac{\sqrt{3}}{3}E_{NC1}+\frac{\sqrt{3}}{3}E_{NC2}+\frac{\sqrt{3}}{3}E_{NC0}$$

$$-\frac{\sqrt{3}}{3}E_{NB1}-\frac{\sqrt{3}}{3}E_{NB2}-\frac{\sqrt{3}}{3}E_{NB0}$$

$$-jE_{NA1}-jE_{NA2}-jE_{NA0}$$

The sum of the positive (subscript 1) sequence terms $=0$ (first column)

The sum of the negative (subscript 2) sequence terms $=-2jE_{NA2}$ (second column)

The sum of the zero (subscript 0) sequence terms $=-JE_{NA0}$ (third column)

Total error for measurement is therefore $-2\times$negative sequence power$-$zero sequence power, as all phases are analyzed the same way.

Appendix III

For the 3-phase 4-wire delta circuit:

$$E=j\omega MI_1-j\omega MI_3+RI_3$$
$$R=\sqrt{3}\omega M$$

The heater current, on balanced polyphase load

$$I_H=\frac{E}{Z}=\frac{2RI_3}{\sqrt{(R+R_H)^2+\omega^2L^2}}$$

where L is the self-inductance of the secondary winding of the mutual inductance. For equal primary and secondary turns $L=M$

Let

$$\frac{R_H}{\omega M}=x$$

$$I_H=\frac{2\sqrt{3}I_3\omega M}{\sqrt{(R+R_H)^2+\omega^2M^2}}$$

$$=\frac{2\sqrt{3}I_3}{\sqrt{(\sqrt{3}+x)^2+1}}$$

The watts dissipated in the heater

$$W_H=\frac{12I_3^2\omega Mx}{3+2\sqrt{3}x+x^2+1}=\frac{12I_3^2\omega Mx}{4+2\sqrt{3}x+x^2}$$

For a maximum

$$\frac{\partial W_H}{\partial x}=0$$

$$4+2\sqrt{3}x+x^2=2\sqrt{3}x+2x^2$$

$$x^2=4$$

$$x=2=\frac{R_H}{\omega M}$$

Therefore, for maximum efficiency $R_H=2\omega M$.

Discussion

G. G. Waite (Sangamo Company, Ltd., Toronto, Ontario, Canada): In this paper the author has called attention to the merits of measuring demand in amperes. On single-phase circuits this has much to commend it. On polyphase circuits the wisdom is debatable.

Why shy away from scaling the meter in amperes? What is wrong with amperes? Almost any customer can comprehend amperes. Is straightforward simplicity conducive to bad customer relations?

It would seem also that the author, by omitting reference to the $\sqrt{\Sigma I^2}$ type of polyphase demand ammeter, sacrificed unnecessarily the value of his paper. This type of ammeter recognizes unbalance, and for this reason is used in several parts of the world.

The author stresses the economy of his "kilovolt-ampere" ampere-demand meter. In fairness it should be pointed out that the $\sqrt{\Sigma I^2}$ ampere-demand meter is much simpler to build and calibrate.

Wm. C. Downing, Jr. (Sangamo Electric Company, Springfield, Ill.): For the measurement of kilovolt-amperes in single-phase circuits, the use of the thermal demand ammeter, scaled in kilovolt-amperes at a nominal voltage, offers a means of measurement, or approximation, at much lower cost than any device which actually involves the measured voltage. This is due not only to the inherent simplicity of the thermal ampere demand meter but, in part at least, to the difficulty involved in measurement of true kilovolt-amperes in single-phase circuits. Though a thermal kilovolt-ampere demand meter operating upon the displaced voltage principle can be, and is, made to operate on single-phase, to the writer's knowledge, it is not made except for a single power factor condition; as such a meter does not have the flexibility afforded by the various power factor taps of the corresponding polyphase meter, its use for the measurement of single-phase kilovolt-amperes, as such, definitely is restricted. This leaves a considerable gap between the thermal ampere demand meter, scaled for an assumed voltage, and meters which combine power and reactive power to introduce the factor of measured voltage in the measurement of single-phase kilovolt-amperes.

In polyphase circuits, however, this situation is altered by the availability of the displaced voltage type of thermal-kilovolt-ampere demand meter, and it may be questioned, therefore, whether ampere demand, as represented by this very ingenious polyphase meter described by Petzinger, offers appreciable savings in comparison to existing types.

A comparison of the displaced voltage type of thermal kilovolt-ampere demand meter, in which the potential transformers serve also for phase shifting, with the polyphase ampere demand meter shows, on the basis of components: two potential and two current transformers and a tap changing device for the kilovolt-ampere meter; two current transformers, one resistor, and an adjustable mutual inductance for the ampere demand meter. This assumes that substantially the same thermal element is involved in either design; actually, they will differ in detail, as both bimetallic coils must be heated in the former type, whereas only the driving coil is heated in the latter. On the other hand, the problem of thermal lagging, to meet the time interval as defined for thermal demand meters, becomes more difficult for ampere demand, as, due to its inherent square scale characteristic, an ampere demand meter shows less than three fourths of the time interval obtained from a watt demand meter of similar construction. It would be of interest to know, therefore, whether this ampere demand meter can be provided in both 15- and 30-minute intervals, as is the displaced voltage type of instrument.

On the basis of testing, the problem is essentially the same: a complete test means a polyphase test. If, in the manufacture of the displaced voltage type meter, the potential tranformers are tested on polyphase, or by an equivalent single-phase test, then subsequent calibrative testing or checking may be made on single-phase by testing as a watt-demand meter on the unity power factor tap; as the transformers are not subject to change, such a single-phase test is generally adequate. It seems likely that some such method can be developed for the polyphase ampere demand meter, as well, to obviate the necessity of polyphase test.

If, in the matter of accuracy on unbalanced voltages, we accept Petzinger's conclusions that the error in the kilovolt-ampere meter is greater than that of the ampere demand meter, still is it not reasonable to expect that, where the regulation of the supply is such that appreciable voltage unbalance may exist, the departure of the actual voltage magnitude from that assumed may be even more of a factor?

As is pointed out in this paper, any ampere demand meter has, inherently, a square scale, which results in limiting the lower end of the scale to perhaps one fourth or one fifth of the maximum scale value. In contrast to this, the displaced voltage kilovolt-ampere meter has a substantially linear scale and provides, therefore, a useful reading range four to five times as great as that of the ampere demand meter with the same degree of reading accuracy. This means that more different capacities must be available in order to cover adequately a wide range of loads; that the load must be estimated with fair accuracy to permit selection of the proper capacity meter; and that more frequent meter replacement, due to variation of maximum demand, must be expected with the ampere demand meter than with the longer range instrument.

Whether these various factors add up to a more economical method of measuring polyphase kilovolt-ampere demand than with the kilovolt-ampere demand meters currently available is a question that will be decided by time and the requirements of the central station industry. In any event, however, Petzinger's paper presents a new and stimulating solution to the problem of kilovolt-ampere demand measurement; the author is to be congratulated upon it.

A. J. Petzinger: Waite has questioned the desirability of measuring ampere demand on polyphase circuits. There seems to be no fundamental reason why this type of metering should be confined to single-phase circuits.

As far as scaling the meter in amperes is concerned, this is quite possible and, in one respect at least, is desirable. That is, if the meters are scaled in amperes, they may be used on a given circuit regardless of whether the nominal voltage is 115 or 120 volts. On the other hand, present practice, in the United States at least, makes kilovolt-ampere-demand a familiar billing term, whereas, ampere demand is not used so widely. Also, kilovolt-ampere marking is preferable in another respect; namely it is more universal. A demand of a given number of amperes represents one quantity on a 120-volt 2-wire circuit, another on a 240-volt 3-wire single-phase circuit, and still another on a 240-volt polyphase 3-wire circuit. When a kilovolt-ampere scale is used, a given number of kilovolt-amperes represents just that, regardless of type of circuit or voltage.

The operation of the meter described is based on the kilovolt-amperes concept insofar as a given kilovolt-amperes load will produce the same deflection regardless of the current which produced it. For that matter the common single-phase thermal ammeter does likewise. A 10-ampere line to line load indicates 10 amperes on an ampere scale, whereas a 10-ampere line to neutral load indicates 5 amperes. As the actual currents are not being indicated anyway, and as the ampere reading really requires definition, it seems simpler and more direct to use the kilovolt-ampere scale. This, however, is an open question, and the ultimate answer probably will be based on the relative merits in practical application.

Waite suggests the use of a $\sqrt{\Sigma I^2}$ meter and states that this type of meter "recognizes" unbalance. The recognition, however, is of very dubious value. The meter described in this paper recognizes unbalance in the sense that the same kilovolt-amperes load gives the same deflection, regardless of which phase or phases are loaded. The recognition advocated by Mr. Waite merely consists of ignoring this principle and assuming that the arbitrary increased reading on an unbalanced load is a proper penalty for unbalance. This idea contains the following two questionable assumptions:

1. That unbalanced load should be penalized.
2. That the size of the penalty should be in cordance with the reading of a $\sqrt{\Sigma I^2}$ meter.

As to the first, it is not clear why unbalanced loads should be considered so objectionable on polyphase circuits but not on single-phase circuits. In fact, the 3-phase 4-wire delta circuit and the 3-wire network circuit basically are provided for unbalanced loads. It seems contradictory to provide a circuit for combined lighting and power and then to penalize a customer for using the facilities provided.

Waite has not made clear just how such a meter would be used on these nonsymmetric services. On a 3-phase 4-wire delta circuit, for example, the use of equal heaters in each line would encourage loading across 208 volts, as it would cost no more than 120 volts. If the resistance of the heater in this phase were made proportionally larger, it is evident that a single-phase line-to-line load would give different read-

ings, depending on which phase was loaded.

If it were granted that unbalance should be penalized, the second assumption—that the size of the penalty should be in accordance, with the reading of a $\sqrt{\Sigma I^2}$ meter—seems to have no basis other than convenience. It would seem to be a remarkable coincidence, if the meter's reading should provide exactly the desired penalty under all unbalance conditions.

A comparison of the cost of the polyphase ammeter type of kilovolt-amperes meter versus the displaced-voltage type shows, as Downing points out, and as the paper also indicates, that the former requires a mutual reactor and a resistor, while the latter requires two combined potential and phase shifting transformers and a tap changing device. Both require current transformers. However, this enumeration of components does not make apparent the difference in cost or size of these components. The thermal ammeter has a pronounced advantage in both respects. In a combination watt-hour and thermal kilovolt-ampere demand meter, particularly, space is important.

Downing calls attention to the basic difference in time interval of an ammeter from a wattmeter of a given construction. It is possible that development of a 30-minute interval device, if required, may be somewhat more difficult than that of the corresponding wattmeter, but this should not prove at all insurmountable.

As far as the effect of voltage is concerned, the paper merely attempted to show that voltage magnitude was the only factor of any consequence. It should be kept in mind that electricity is distributed on a constant voltage basis and not on a constant power factor basis. A displaced voltage meter, therefore, requires a certain amount of checking to determine the proper tap setting and assumes that the power factor will be reasonably close to the setting.

The paper also called attention to the scale limitations mentioned by Downing. Assuming, as did Downing, that the lower end of the scale would be limited to one fourth of full scale, it is difficult to accept his conclusion that the useful range of a linear scale meter would be four times as great. For example, if the full-scale value of an ammeter were 30 amperes, the lowest reading permissible, on this basis assumed, would be $7^1/_2$ amperes. A linear scale meter, on the equivalent basis, could be read to 2 amperes. The useful range of the ammeter, therefore, would be $22^1/_2$ amperes, whereas that of the displaced voltage meter would be 28 amperes. The range of the ammeter is, therefore, 80 per cent, of that of a linear scale meter. It is doubtful that this would affect the number of capacities required, the estimation of loads, or the frequency of meter replacements to any considerable extent.

The discussions should be of value in clarifying the field of application for the polyphase thermal ammeter. The ultimate decision, of course, will rest with the users, and this meter has been described as a new alternative which undoubtedly will find considerable application.

Electrical Characteristics of the Junction in a Simplified Selenium Rectifier Cell

STEPHEN JAMES ANGELLO
ASSOCIATE AIEE

Synopsis: The selenium-cadmium contact is a simplified version of the commercial selenium rectifier and is studied with the purpose of understanding the physics of contact resistance asymmetry. A theory by W. Schottky, which predicts the contact resistance at zero voltage and the course of this resistance with d-c reverse bias, is not adequate to account for the experimental data. An attempt is made to extend the theory by assuming a fraction of the bromine ions in the selenium to be free. Agreement with experiment is obtained for low voltages at a high temperature, but for high voltages at all the temperatures employed there is marked disagreement. The theory developed is sufficiently general to conclude that the contacts studied have either a polarizable layer less than 10^{-5} centimeter thick between the cadmium and selenium, or there is a mechanism of deactivation of bromine ions at higher voltages. The experiments do not distinguish between the alternatives.

THE PURPOSE of this paper is twofold.

1. To present data on the capacitance and resistance of a selenium-cadmium contact which can be compared with the theoretical predictions made by W. Schottky.[1]

2. To extend Schottky's theory in an attempt to obtain quantitative agreement between the theory and experimental data.

Metallic selenium containing 0.01 per cent by weight of bromine is a semiconductor[2] with a conductivity of approximately 4×10^{-2} mho per centimeter at 25 degrees centigrade. A pure cadmium electrode sprayed on the selenium results in a contact which has a resistance of about 4×10^{4} ohms for one square centimeter at zero volts. The contact resistance is dependent on the voltage applied to the contact and exhibits a remarkable asymmetric variation of values depending on the sense of voltage. Details of the preparation of samples for this work are given in Appendix I.

The simple selenium-cadmium contact should fulfill the conditions on which Schottky's theory is based, but the experimental data are in serious disagreement with predicted results.

Theory

Differential Resistance

Schottky[1] has shown that the relation between the current i through a selenium-cadmium contact and the voltage U applied is

$$i=\sigma_R E_R \frac{1-exp(-U/B)}{1-[exp-(U+V_D)/B]} \tag{1}$$

where

$\sigma_R = n_R e b$
n_R = electron density in the selenium at the metal junction
e = electronic charge
b = electron mobility (average velocity per unit field strength)
$B = kT/e$
k = Boltzmann's constant
T = absolute temperature
$V_D = -B\ ln(n_R/n_R)$
n_R = electron density in the selenium far from the contact
E_R = the electric field strength at the junction

In this paper interest is centered on the high resistance direction for which $U=+U_h$. The constant V_D is known to be much greater than B. Hence

$$i_h=\sigma_R E_R[1-exp(-U_h/B)] \tag{2}$$

An important concept is the differential resistance R defined by

$$R=\left.\frac{dU}{di}\right|_i \tag{3}$$

For the special case of low voltage ($U_h<B$), equation 2 can be written

$$i_h=\sigma_R E_R(U_h/B) \tag{4}$$

and an application of equation 3 yields the resistance at zero volts

$$R_0=\left.\frac{dU}{di}\right|_{i=0}=B/\sigma_R E_R \tag{5}$$

Applying equation 3 to equation 2 permits evaluation of the differential resistance at any voltage in the high resistance direction. The result is

$$R=\frac{2V_D R_0}{B}\frac{(1+U_h/V_D)^{1/2}}{\{1+exp(-U_h/B)\times[(2V_D/B)(1+U_h/V_D)-1]\}} \tag{6}$$

The differential resistance can be measured directly with the a-c bridge described in Appendix II.

Field Strength E_R

Contemporary theoretical discussions of the selenium-cadmium contact agree that the cadmium metal causes an electron redistribution in the selenium at the boundary which results in a thin layer of negative space charge in the selenium. This charge may be associated with ionized bromine which purposely was added to the selenium to modify the electrical properties. Schottky assumes that the bromine ions are distributed uniformly and fixed in position. As there is a space charge density $\rho(x)$ in the boundary layer, the electric field $E(x)$ is given by the Poisson relation

$$\frac{dE(x)}{dx}=-(4\pi/\epsilon)\rho(x) \tag{7}$$

Paper 47-26, recommended by the AIEE committee on electrochemistry and electrometallurgy for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted October 15, 1946; made available for printing December 3, 1946.

Stephen James Angello, formerly a research engineer with Westinghouse Research Laboratories, is now an assistant professor of electrical engineering at the Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, Pa.

The author gratefully acknowledges the support of Westinghouse Research Laboratories where the work was carried out and the preparation of the selenium-cadmium contacts by Theodore Ebert of the same laboratory.

Figure 1 (left). Experimental data compared with data computed from Schottky's formula, equation 6

Figure 2 (above). Selenium-cadmium contact capacity variation with reverse voltage

Selenium-cadmium contact E626

where κ is the dielectric constant of selenium. The development is confined to the case in which $\rho(x)=eN_D$, where N_D is the bromine ion density and is constant through the selenium.

It is convenient to introduce the potential $V(x)$ defined in the usual way so that

$$\frac{d^2V(x)}{dx^2}=(4\pi/\kappa)eN_D \tag{8}$$

Multiplying both sides of equation 8 by dV/dx gives

$$\left(\frac{dV}{dx}\right)\left(\frac{d^2V}{dx^2}\right)=\frac{d}{dx}\left[\frac{1}{2}\left(\frac{dV}{dx}\right)^2\right]=(4\pi/\kappa)eN_D\frac{dV}{dx} \tag{9}$$

Both sides of equation 9 can be integrated to obtain

$$\left(\frac{dV}{dx}\right)^2=(8\pi/\kappa)eN_DV+\text{constant} \tag{10}$$

At a distance from the contact where the cadmium does not affect the electron distribution in the selenium, $V(x)$ and $dV(x)/dx$ are zero. Hence the constant is zero. Finally,

$$E_R=\left.\frac{dV}{dx}\right|_{x=0}=[(8\pi/\kappa)eN_D(V_D+U_h)]^{1/2} \tag{11}$$

Using equation 11, the null resistance of equation 5 becomes

$$R_0=\frac{B}{{}_R(8\pi eN_D/\kappa)^{1/2}V_D^{1/2}} \tag{12}$$

If the quantities N_D and V_D can be found, enough data is available to compute R_0. The theory underlying the determination of these quantities is described in the next section on capacity.

Capacity

The boundary layer of a cadmium-selenium contact behaves as a parallel resistance and capacitor to the alternating voltage employed in the bridge. The capacitance of the contact is given by

$$C=\kappa/4\pi l_k \tag{13}$$

Where l_k is the thickness of the boundary layer, that is, the region influenced by the cadmium. Using the Poisson equation 7 and mathematical manipulation given in Appendix III, the following important result is obtained:

$$\frac{d(1/C^2)}{dU}=\frac{8\pi}{\kappa e}\times\frac{1}{N_D} \tag{14}$$

Figure 3. The apparent voltage V_a for three temperatures of the contact

Equation 14 discloses that a plot of the reciprocal of capacitance squared as a function of voltage applied to the contact should be a straight line in this case. The quantity N_D can be computed from the slope. The constant V_D is the intercept of this line on the voltage axis. From equation 1 it can be seen that the junction resistance disappears when $-U=V_D$. This implies that the boundary layer has disappeared and C is infinite.

With the a-c bridge described in Appendix II, both R and C can be measured simultaneously for values of d-c bias voltage applied across the contact.

A New Assumption for the Space Charge

In equation 8, N_D is assumed to be constant. If it be supposed that there is a fraction F of the N_D bromine ions free to move in the electric field $E(x)$, there will be a distribution of charge density $eN_D(x)$ which is dependent on the applied voltage and V_D. The condition may be expressed mathematically as follows:

$$\rho(x)=eN_D[1+F\varphi(V(x)/B)] \tag{15}$$

where φ is any continuous function of $V(x)$. With this added term the determination of E_R may be carried out in a more general way. Equation 8 becomes

$$\frac{d^2V(x)}{dx^2}=(4\pi/\epsilon)eN_D[1+F\varphi(V(x)/B)] \tag{16}$$

which may be solved in the previous manner, namely,

$$\left(\frac{dV}{dx}\right)\frac{d^2V}{dx^2}=\frac{d}{dx}\left[\frac{1}{2}\left(\frac{dV}{dx}\right)^2\right]$$
$$=(4\pi/\kappa)eN_D\left[\frac{dV}{dx}+F\left(\frac{dV}{dx}\right)\varphi\right] \quad (17)$$

Integration yields

$$\left(\frac{dV}{dx}\right)^2=(8\pi/\kappa)eN_D\left[V(x)+FB\int\varphi\left(\frac{V}{B}\right)d\left(\frac{V}{B}\right)+\text{constant}\right] \quad (18)$$

Under the same boundary conditions as before, the constant is

$$-\int\varphi\left(\frac{V}{B}\right)d\left(\frac{V}{B}\right)\Big|_0 \quad (19)$$

so that

$$\frac{dV}{dx}=\left\{(8\pi/\kappa)eN_D\left[V(x)+FB\int_0^{V/B}\varphi\left(\frac{V}{B}\right)d\left(\frac{V}{B}\right)\right]\right\}^{1/2} \quad (20)$$

Finally, at $x=0$

$$E_R=\left(\frac{8\pi eN_D}{\kappa}\right)^{1/2}\left[U_h+V_D+FB\int_0^{V(0)/B}\varphi\left(\frac{V}{B}\right)d\left(\frac{V}{B}\right)\right]^{1/2} \quad (21)$$

An interesting result of this development is that the voltage $V(0)=(U_h+V_D)$ under the radical is increased by a new voltage V_a given by

$$V_a=FB\int_0^{V(0)/B}\varphi\left(\frac{V}{B}\right)d\left(\frac{V}{B}\right) \quad (22)$$

If there are no free bromine ions, that is, $F=0$, then equation 21 becomes equation 11.

The result is very general; indeed, the term $eN_DF\varphi(V/B)$ need not be attributed to free bromine ions, but to any kind of polarizable layer at the junction. This topic is more appropriate under the discussion of results. If the assumption of a fraction of free bromine ions is followed, it is shown in Appendix IV that

$$V_a=BF[\exp(V_D/B)]^{(1+U_h/V_D)} \quad (23)$$

Final Expression for the Differential Resistance

Thus far, the theory has not taken into account the potential of the image force between conduction electrons in the selenium and the cadmium metal. N. F. Mott[3] has shown that this may be included by multiplying σ_R of equation 12 with the factor

$$\exp\left[\frac{e^{3/2}E_R^{1/2}}{\kappa^{1/2}kT}\right] \quad (24)$$

where e is the electronic charge.

If the possibility of an apparent voltage being added to V_D is taken into account, the final form for R_0 is

$$R_0=\frac{B}{\sigma_R\exp\left[\frac{e^{3/2}E_R^{1/2}}{\kappa^{1/2}kT}\right](8\pi eN_D/\kappa)^{1/2}(V_D+V_a)^{1/2}} \quad (25)$$

where E_R is given by equation 21 and R becomes

$$R=\frac{2(V_D+V_a)R_0}{B}\times\frac{[1+U_h/(V_D+V_a)]^{1/2}}{\left\{1+\exp(-U_h/B)\left[\frac{2(V_D+V_a)}{B}\times\left(1+\frac{U_h}{V_D+V_a}\right)-1\right]\right\}} \quad (26)$$

Experimental Results

Differential Resistance and the Voltage V_a

The discrepancies which exist between measured values of differential resistance and theoretical predictions are displayed clearly by Figure 1. The measured resistance at zero voltage is two orders of magnitude higher than that predicted, and the course of the resistance with increasing reverse voltage is different.

Figure 2 shows that the linear $1/C^2$ versus U law of equation 14 is obeyed up to 0.5 volt, after which another straight line is followed. One may say that the slight change in slope indicates a small

gradient of bromine ion density. Computation yields a value of N_D equal to 1.48×10^{16} ions per cubic centimeter. This agrees well with 2.47×10^{16} found by W. E. Blackburn (in his thesis presented to the department of Physics, University of Pittsburgh, entitled "Temperature Coefficient of Electrical Resistivity for Crystalline Selenium Containing Various Percentages of Bromine") using an electron mobility of one centimeter/second/volt/centimeter given by Schottky.[1] The bromine ions in the boundary layer are all ionized, and Schottky's theory should apply to this case.

The failure of equation 12 to predict the resistance at zero voltage indicates that conditions exist in the contact which have not been considered. The marked effect of small amounts of bromine vapor on the electrical properties of the contact, to be discussed later, lead to the supposition that there are some free bromine ions in the contact. The consequences of this were discussed under "Theory—A New Assumption for the Space Charge." An important result is that V_D is increased by an apparent voltage V_a as set forth in equation 25. It is not at present possible to compute an a priori value for Va using equation 23, because the value of F, the fraction of ions free, is not known. However, if it be assumed that R_0 in equation 25 is the measured value, then V_a can be computed for reverse voltages through equation 23. As the form of the function φ is not certain, it is best to put the measured values of R into equations 25 and 26 to compute V_a as a function of reverse voltage.

Such computations have been made and the results for one sample at three different temperatures is shown in Figure 3. The theoretical expression for V_a is followed up to about 0.2 volt when the contact is at 47.1 degrees centigrade. A rapid deviation occurs at higher voltages. At lower temperatures the exponential law is only approximately obeyed below 0.2 volt. This will be treated further under "Discussion."

The data used in the computations described are plotted in Figure 4. The shape of the curves as well as the null resistance is temperature dependent. It is interesting that the curve for −4.5 degrees centigrade crosses the room temperature curve at about two volts. This phenomenon is probably caused by the image force potential expressed by the Mott factor 24 multiplying σ_R in equation 25.

Effect of Forming, Heat Treatment, and Bromine Vapor on the Bromine Ion Density N_D

Forming is an electrical process whereby the reverse current of a rectifier at a given reverse voltage is caused to decrease permanently. The selenium-cadmium contact sample was formed by a 3-step process.

1. A reverse voltage of 13 volts was applied which gave 2.5 amperes of reverse current initially.
2. The voltage was advanced uniformly to 32 volts in about $2^1/_2$ hours.
3. The rectifier was operated for one-half hour at 32 volts. After this treatment, the current at 13 volts was one-half ampere.

Figure 5 demonstrates clearly that bromine ions are lost to the boundary layer because of the forming treatment. The configuration of signs in the boundary layer when a reverse voltage is applied is shown in Figure 6. One would expect some movement of bromine ions toward

the cadmium. Evidently, some bromine escapes through pores in the metal.

That escape is possible, and the process is reversible to some extent, is demonstrated strikingly by the following experiment. An unformed disk was heated to 205 degrees centigrade for two hours. After capacity measurements, the same disk was exposed to vapor from a bottle containing bromine. The results are illustrated in Figure 7. The selenium lost bromine through heat treatment, but got back more than the initial amount after bromine vapor exposure.

Discussion

The forming, heat treating, and bromine vapor tests show conclusively that bromine ion movement plays an important role in selenium-cadmium contact phenomena. It is not clear whether or not free ion movement is sufficient to explain all the phenomena. The V_a curves of Figure 3 show that if the free ion hypothesis is correct, then a mechanism for temporarily removing bromine from active participation is necessary. For example, bromine ions may coalesce into inactive bromine atoms at the contact because of the high density, or clusters of ions might be formed.[4] If further work should show that the hypothesis is untenable, then the required voltage V_a could be ascribed to a polarizable layer at the contact. It would be of especial interest to try to make a rectifier in vacuum taking care to have no contamination between the cadmium and selenium which would be polarizable. In this case the data should agree better with the Schottky theory, unless free bromine ions have an important effect on the contact resistance.

Appendix I. Preparation of Selenium-Cadmium Contact Samples

The semiconducting material is prepared from pure double-distilled selenium to which is added 0.01 per cent by weight of bromine. An 0.002–0.003-inch layer of this material is spread on a nickel plated iron disk at 350 degrees centigrade and rapidly cooled. The disk is 1/32 inch thick and $2^1/_8$ inches in diameter with a 3/8-inch center hole. Pure cadmium metal is sprayed over 18.7 square centimeters of the surface of the selenium at room temperature. The vitreous modification which results must be converted to the metallic form by annealing below the melting point.

Upon completion of the disk the junction between the selenium and nickel plate is of low resistance and nonrectifying, so that it need not be considered in this paper.

Appendix II. A-C Bridge for Contact Resistance and Capacity Measurements

The special form of a-c bridge used for the experiments is shown in Figure 8. A substitution method is used to obtain directly the equivalent parallel resistance and capacity of the contact. The 1,000-cycle signal generator output is adjusted to give 40 millivolts rms across the 0.5-ohm resistor. Such a low voltage is necessary because the rectifier is a nonlinear element. For voltages less than kT/e it will appear in the bridge as a linear resistance and capacity combination.

In order to obtain an accurate bridge balance, a high gain amplifier is employed. An unconventional feature is that a 1,000-cycle band pass filter is connected across the output to reject noise from the amplifier and rectifier. Electrical noise is generated by the rectifier when reverse voltage is applied. This obscures the bridge null for reverse voltages on the rectifier larger than five volts and impairs the precision of the measurements.

Provision is made for a constant d-c bias voltage on the rectifier without affecting the a-c performance of the circuit.

Appendix III. Capacitance and Bromine Ion Density N_D

Integrating equation 7 across the boundary layer gives

$$E(x) = -\frac{4\pi}{\kappa}\int^{l_k} \rho(x)dx \tag{27}$$

The boundary layer thickness l_k is a function of the applied voltage. Hence it is convenient to change the variable in equation 27 to l_k. Suppose that the integral can be found and is $L(x)$. Then

$$E(x) = (-4\pi/\kappa)[L(l_k) - L(x)] \tag{28}$$

and differentiation with respect to l_k give

$$\frac{dE(x)}{dl_k} = -\frac{4\pi}{\kappa}\frac{dL(l_k)}{dl_k} \tag{29}$$

for a change in $E(x)$ at x. Hence

$$\frac{dE(x)}{dl_k} = (-4\pi/\kappa)\rho(l_k) \tag{30}$$

The change in $E(x)$ at x caused by U is

$$dE(x) = dU/l_k \tag{31}$$

Using equation 30 one obtains

$$dU = (-4\pi/\kappa)\rho(l_k)l_k dl_k \tag{32}$$

Introducing C for l_k through equation 13 results in

$$\frac{d(1/C^2)}{dU} = -\frac{8\pi}{\kappa}\frac{1}{\rho(l_k)} \tag{33}$$

Appendix IV. Derivation of the Formula for V_a

If an ion current i_t exists, it will be given by

$$-i_t = eb_t\left[n_t(x)E_t(x) - B\frac{dn_t}{dx}\right] \tag{34}$$

where

b_t = the mobility of the ions
n_t = density of ions free to move
$E_t(x)$ = the appropriate electric field

In the case of zero voltage, $i_t = 0$ and

$$\frac{dn_t}{n_t} = -\frac{E_t(x)}{B}dx \tag{35}$$

The integral of this is

$$\int_{n_{tx}}^{n_{tH}} \frac{dn_t}{n_t} = ln\left(\frac{n_{tH}}{n_t(x)}\right) = -\frac{V_t(x)}{B} \tag{36}$$

where n_{tH} is the free ion density far from the contact. If the function φ of equation 15 be written as

$$\frac{n_t(x)}{n_{tH}} = \varphi = exp[V_t(x)/B] \tag{37}$$

utilizing equation 36. Then equation 22 becomes

$$V_a = FB\int_0^{(V_D+U_h)/V_D} exp(V_t/B)d(V_t/B)$$
$$= FB\{exp[(V_D+U_h)/B]-1\} \tag{38}$$

Unity can be neglected against $exp(V_D/B)$ which results in

$$V_a = FB[exp(V_D/B)]^{(1+U_h/V_D)} \tag{39}$$

Automatically Controlled Copper-Oxide Rectifiers for Electroplating and Anodizing Applications

JOSEPH J. BUCKLEY
ASSOCIATE AIEE

IN large electroplating or anodizing installations where the tank current is of the order of thousands of amperes, consideration should be given to a d-c power supply which is completely automatic in its operation. By eliminating the human element, rejects are reduced to a minimum; this in itself frequently justifies the higher initial investment. Moreover, a more uniform quality of work is produced. This paper describes the copper-oxide rectifiers used in applications of this type and several of the more common circuits whereby the d-c output is controlled.

Components

The essential components of an automatically controlled installation are

1. One or more copper-oxide rectifier units.
2. An induction type control.
3. An a-c contactor.
4. An operator's control box.

The first two items will be treated in detail in subsequent paragraphs following a brief résumé of rectifier fundamentals.

Copper-Oxide Rectifier

A fan-cooled basic 3-phase bridge, consisting of six copper-oxide cells, has an almost universally accepted rating of 6 volts direct current. This provides an ample margin of safety between the inverse voltage impressed across the cell when not conducting and the breakdown voltage. By a coincidence, this rating ties in very well with the majority of still tank plating applications, copper, nickel, tin, cadmium, zinc, and so forth, which require a voltage generally between three and six volts.

A sufficient number of cells may be connected in parallel to obtain the desired current rating. A series connection also may be used if higher voltages are required; for example, two cells in series are used for barrel plating or electrolytic cleaning at 12 volts.

Figure 1 illustrates a stack consisting of 26 copper-oxide cells, $4^3/_8$ by 5 inches in size, strung on an insulated bolt and connected in parallel. For simplicity the end brackets are live; thus the stack is connected up at the same time that it is mounted. Six of these stacks comprising a 3-phase bridge, have a fan-cooled rating of 6 volts, 500 amperes maximum. A stack with 4 cells in series and 7 in parallel which is used for anodizing applications at 24 volts (also 40 volts by connecting 2 in series) is shown in Figure 2.

Rectifier Unit

The rectifier unit is a simple assembly of stacks, rectifier transformer, ventilating fan, and air switch. The most popular model for automatically controlled power supplies is shown in Figure 3. It occupies less than seven square feet of floor space, stands five feet four inches high, and weighs about 1,100 pounds. A special foundation for supporting and anchoring the unit is not required. With the exception of the fan, there are no moving parts such as bearings, brushes, or commutator, so that maintenance is reduced to a minimum. As the air enters at the bottom and is discharged at the top, the two banks of stacks are located in the lower part of the unit in order that the operating temperature of the copper-oxide cells will be only 2 to 6 degrees centigrade above the room temperature. Each bank is a complete 3-phase bridge, consisting of 12 stacks similar to those shown in Figures 1 and 2. The rating of each bank is 6 kw direct current. Because the 2 banks can be connected in series or in parallel externally, the unit has a dual output rating such as 6 volts, 2,000 amperes and 12 volts, 1,000 amperes. Above the stacks is a 20-kva 3-phase transformer with 2 secondary windings, each feeding a-c power to a bank. If the fan fails, the air switch will drop down, opening the interlock circuit and disconnecting all units of the installation from the 3-phase a-c supply.

The variation in direct voltage with load current for this unit with a fixed alternating voltage and a load of varying resistance is given at the top of Figure 4. This is an average curve for a new unit. Some units will have a regulation as low as 20 per cent and others after aging may run as high as 38 per cent. If a particular unit is set for 6 volts with a full tank load and the operator starts removing work, the voltage will rise and, if there is no overvoltage relay for protection, the voltage may be as high as 7.5 at light load. This is a very undesirable condition both from the standpoint of the rectifier which has a high inverse voltage impressed across the cells, and the electroplated coating which may be burned or blistered because of the excessive current density. Some method of reducing the alternating voltage, either manually or automatically, as the load is decreased must be employed. A suitable circuit has been developed whereby a special type of motor driven

induction voltage regulator, called an induction type control, automatically maintains a constant direct voltage within limits of $2^1/_2$ per cent or better. A number of installations of this type are now in service and operating very successfully.

Induction Type Control

Induction type controls have been used in conjunction with copper-oxide rectifiers for installations varying from 6 to 210 kw capacity. The size of the control varies depending on the d-c power and also the output range that is maintained; for example, a control which maintains the voltage between four and six volts is relatively small whereas one which holds the voltage anywhere between one and six volts is nearly twice as large. Figure 5 shows a typical one which controls three 12-kw rectifier units. The essential components of the control are the series windings which are connected in series with the control output, and the shunt windings which are connected in Y across the 3-phase a-c supply lines. The voltage induced in each series winding is constant in magnitude but varies in its phase relation with the corresponding supply voltage as the position of the rotor with respect to the stator is changed. The output voltage of the control is the vector sum of the supply voltage and the series winding voltage. As the vector position of the series winding voltage is varied from being in phase to 180 degrees out of phase with the supply voltage by means of the operating motor, the output voltage is decreased continuously from maximum to minimum.

The brain of this type of d-c power supply is the contact-making instrument which is mounted on the panel inside of the control. This consists of a solenoid having an iron core suspended from a spring, and a pivoted beam incorporating a set of single-pole double-throw contacts which is caused to rotate by the up and down motion of the core. A direct or alternating voltage applied to the solenoid causes an upward electromagnetic pull to be exerted on the core. Hence, with normal current through the solenoid, the spring force plus the electromagnetic force just balance the weight of the core, and the beam is horizontal. If the solenoid current deviates from its normal value, either the left or the right hand beam contacts will close, and the operating motor will turn the rotor just enough to correct the situation. Basically then, the contact-making instrument maintains a constant solenoid current.

Control Circuits

By using a solenoid whose voltage drop with normal current through it is slightly less than the minimum rated voltage of a d-c power supply under consideration, and connecting in series with it a variable resistance whose maximum value is such that the voltage drop across it with normal solenoid current flowing is slightly more than the difference between the maximum and minimum rated direct voltages, a constant voltage circuit is created which is completely independent of load resistance variations or line voltage fluctuations. Figure 6 illustrates the principle of operation of the essential elements of such a circuit. For simplicity a single-phase a-c supply is shown and a single-phase bridge rectifier. The motor control relay is added to reduce the current burden of the voltmeter contacts so that the life will be increased greatly. The coils of this relay are energized by the beam contacts and through one or the other of its contacts the necessary current for the operating motor passes. Both the relay and the voltmeter are shown in the de-energized position. Any voltage between the maximum and minimum value is maintained by merely setting the voltage level rheostat. The absolute ratio of maximum to minimum voltage is equal to the ratio of the sum of solenoid and rheostat resistances to solenoid resistance.

When the a-c power of this basic circuit is opened, the "raise" contacts of the voltmeter will close, the "raise" relay coil will be energized (if the no-voltage relay were not in the circuit, the connection between the voltmeter and the "raise" coil would be unbroken), and the rotor will advance all the way to the maximum voltage position without stopping. The next time the a-c power is closed, a high voltage will be impressed on the rectifier for a few seconds until the operating motor drives the rotor back down to the proper point. To prevent this undesirable occurrence, a no-voltage relay is connected into the circuit. When the a-c power is opened, this relay is de-energized, opening the "raise" coil circuit and applying a-c power directly to the "lower" coil. Thus the control resets itself in the minimum voltage position every time the operator presses the stop button at the conclusion of a work cycle. This constant voltage circuit is the most common one for plating applications.

If the control output current is plotted as a function of the direct current, the resulting curve is, for all practical purposes, a straight line passing through the origin. Furthermore, it is independent of the direct voltage. Therefore a circuit which controls the control output current is a constant current circuit. Detail 1 of Figure 6 illustrates how the fundamental constant voltage circuit is modified to accomplish this. That portion of the resistance connected across the current

transformer secondary winding is decreased to increase the direct current. Any current between 40 per cent and rated value is maintained by merely setting the rheostat; by using a multiple winding current transformer, current ranges of 5 to 1 and even 15 to 1 can be controlled. This type of control is used for sulphuric acid anodizing because it is not feasible to impress 18 to 24 volts across the load initially. There would be a heavy overload in current until the oxide film built up sufficiently to increase the load resistance materially. By maintaining the current, the d-c power supply is always within its rating. The circuit also has been used for plating where the work consists of large pieces or a continuous strip. The proper current density is maintained even though the solution varies or the anodes wear down.

It is customary with the chromic acid process to anodize for a definite period of time at 40 volts once the anodic film is established. During the initial build-up period when the load resistance increases many fold, constant current control is best. This enables the build-up to be accomplished in the shortest possible time without overloading the d-c power supply. This requires additions to the fundamental circuit shown in detail 2 of Figure 6. For the first five minutes or so of the anodizing cycle the voltage relay is not energized, and the control circuit is identical with that shown in detail 1 of Figure 6. But once the voltage is up to 40 volts, the relay picks up causing the time switch motor to start and the transfer relay to function. The solenoid is now in series with the voltage level rheostat instead of being in parallel with the current level rheostat, and the contact-making instrument is a voltmeter. At the end of the preset time interval, the time switch shuts off the a-c power, and the control resets itself for the next cycle.

Installation

To obtain the desired tank power, a number of units can be connected together with their outputs in parallel, in series, or by a combination of the first two methods. All the units which make up the installation invariably are connected in parallel on the input side and are supplied with an automatically varying alternating voltage from the induction type control. Anywhere from 1 to 18 units have been used with a single control.

The combined efficiency of such an installation (stack forward and reverse loss, rectifier transformer copper and core loss, induction type control copper and core loss) as a function of direct current both at rated voltage and one-half voltage is shown by curves *A* and *B* in Figure 4. The rectifier fan loss is not included because separate voltage circuits are used for auxiliaries; it is only 2.4 per cent of the rectifier output. The power loss of all other auxiliaries is negligible. The metallic rectifier maintains a high efficiency from very light load to rated load and even at overload, and is superior to all other sources of low voltage d-c power in this respect. It is suited ideally to electroplating and anodizing because the load is likely to vary considerably.

The over-all power factor versus load curves are shown at the bottom of Figure 4. The departure from unity is caused in part by the displacement between voltage and current because of the induction type control and the rectifier transformer and in part by the harmonic content in the a-c line current because of the rectifier. For operation between one-half the rated current and rated current and one-half the rated voltage and rated voltage, the

power factor is between 70 and 90 per cent This is considerably higher than the corresponding values for a saturable reactor type of control.

Figure 7 is an elementary diagram showing how the four components (for simplicity only one rectifier unit is depicted) are integrated to make up a complete d-c power supply. Only the control box needs to be located close to the tank because normally the operator uses only the start and stop push buttons. The rectifier units and the induction type control should be installed in a clean place, preferably a separate room, where they will not be subject to corrosive fumes or excessive moisture and where ventilation is adequate. To make sure the units are not operated at a voltage in excess of the rated value, an overvoltage relay is added with its normally-closed contacts in the interlock circuit.

An Analysis of Motor Selection for Brass-Slab Rolling-Mill Service

L. H. BERKLEY
ASSOCIATE AIEE

IT is the purpose of this paper to outline some of the problems and calculations encountered by the author in selecting a motor drive for a brass-slab rolling mill. It is hoped that some of the information given will be useful to other engineers faced with similar problems.

Description of the Rolling Mill

A description of the mill will aid in understanding the problem. (See Figure 1.)

The mill is of an old design but has been kept in excellent running condition. It consists essentially of a 2-stage speed reduction unit to step down from the speed of the motor (600 rpm) to the speed of the rolls ($12^1/_2$ rpm). The intermediate gears rotate at 82 rpm and carry a 14-foot flywheel. There are two stands of 2-high rolls to permit rolling two slabs simultaneously.

Present Motor

The mill is driven at present by a Westinghouse squirrel-cage induction motor, 250 horsepower, 580 rpm, 2,200 volts, 3 phase, 60 cycles, 57.5 amperes. The characteristics of the motor were obtained from the manufacturer as follows:

Full load power factor = 87 per cent
Full load efficiency = 90 per cent
Full load input = 100 per cent, 191 kw
Full load current = 100 per cent, 57.5 amperes
Full load torque = 100 per cent, 2,260 pound-feet
Starting current = 600 per cent, 365 amperes
Starting torque = 110 per cent, 2,490 pound-feet
Pullout torque = 250 per cent, 5,750 pound-feet
Pullout speed = 520 rpm
Pullout power factor = 74 per cent
Pullout efficiency = 63 per cent
Pullout input = 700 kw
Moment of inertia of rotor = 2,300 pound-feet
Weight of rotor = 1,600 pounds

As the effectiveness of the flywheel increases with the slip of the motor driving the mill, the question naturally arises as to why a flywheel was used with a motor having such a small full load slip ($3^1/_2$ per cent). The reason is that the mill originally was driven by a single-stroke Corliss steam engine driving the intermediate shaft at about 80 rpm and the flywheel was necessary to smooth out the load peaks and to help maintain constant speed during the rolling operation. As will be shown later, the power generated by the flywheel during the rolling peak is quite appreciable. The present motor replaced the steam engine in 1917, which necessitated adding the second set of gears, and has been driving the mill at an average of 48 hours per week since then. The motor is living "on borrowed time", so to speak, and it was considered advisable to purchase a replacement to be used in case of breakdown.

Possibilities

In considering the purchase of a new motor, four possibilities were apparent.

1. Standard squirrel-cage induction motor, similar in characteristics to the old motor [NEMA (National Electrical Manufacturers Association) type *A*].
2. High-slip squirrel-cage induction motor (NEMA type *D*).
3. Wound-rotor induction motor.
4. Synchronous motor.

Before a decision was reached, the torque-speed characteristics of each motor had to be considered. From the known data of the present motor, its characteristic was constructed as shown in Figure 2.

The second possibility is the high-slip squirrel-cage motor, whose characteristic also is shown in Figure 2.

The third possibility, the wound-rotor motor, offered the advantages of most rapid acceleration during the starting period and also of variable speed. Because neither rapid acceleration nor variable speed were especially desirable, and because the equipment would be more expensive in first cost and maintenance, the wound-rotor motor was ruled out.

The last possibility, the synchronous motor, looked very favorable as an 80-per-cent-power-factor motor and controls would cost little more than the standard squirrel-cage motor and controls and would offer a leading power of about 150 kva from no load to full load, whereas the induction motor would offer about 100

Figure 1. Schematic plan view of mill

Figure 2. Torque-speed curves of squirrel-cage induction motors

These curves may vary considerably within the same NEMA classification

kva lagging. However, it was decided inadvisable to use the synchronous motor because of the sustained jogging required to remove a slab that may become stuck between the rolls when a coupling breaks. This jogging would all be done on the damper windings of the motor, which could not be made to stand such severe service.

The two remaining possibilities were that of the standard and the high-slip squirrel-cage motors. Before a choice could be made between the two, a load test had to be run and several calculations made.

Load Test. A load test was run using slabs in the hardest condition (just prior to annealing) with results as shown in Figure 3. It should be noted that the maximum input when rolling two slabs simultaneously is about 300 kw. This represents a peak load of about 325 horsepower or about 30 per cent overload on a 250-horsepower motor.

Calculation of Effective Inertia

Of course, in any application involving a flywheel, the first question the motor manufacturer asks is—"What is the inertia of the load referred to the motor shaft?" This may be determined by two methods.

1. By measuring the dimensions of the flywheel, gears, and so forth, and calculating their effective inertia with respect to the motor shaft.
2. By an experimental method.[1]

To check, it was decided to use both methods.

Measurement

Figure 4 shows a simplified cross-sectional view of the flywheel. To obtain the moment of inertia, it is necessary to calculate the weight and the radius of gyration. The rim only will be considered in making these calculations because therein lies about 95 per cent of its inertia.

Radius of Gyration

Considering X as the distance from the end of the flywheel to the center of gravity G, the following equation is obtained from elementary physical considerations:

$$X = \frac{(13\times4^1/_4)(2^1/_8)+(10\times8)(8^1/_4)}{(13\times4^1/_4)+(10\times8)}$$
$$= 5.74 \text{ inches}$$

The radius of gyration R is then

$$R = 86 - 5.74$$
$$= 80.26 \text{ inches}$$

Weight

Cross sectional area $= (13\times4^1/_4)+(10\times8)$
$= 135.2$ square inches

Mean circumference $= 2\pi\times80.26$
$= 505$ inches

Volume $= 505\times135.2$
$= 68{,}250$ cubic inches

Density $= 0.260$ pounds per cubic inch (for cast iron)

Weight $(W) = 68{,}250\times0.260$
$= 17{,}740$ pounds

Moment of Inertia

$$WR^2 = 17{,}740\times\left(\frac{80.26}{12}\right)^2$$
$$= 795{,}000 \text{ pound-feet}^2$$

The effective inertia at the motor shaft is inversely proportional to the square of the speed ratio. Therefore,

$$\text{Effective } WR^2 = 795{,}000\times\left(\frac{82}{600}\right)^2$$
$$= 14{,}900 \text{ pound-feet}^2$$

This is the inertia of the flywheel rim only and does not include the flywheel spokes or the gears of the system.

Experimental Methods

The following formula was derived by the author in reference 1:

$$WR^2(\text{pound-feet}^2) = 21.65\times10^6\times\frac{P_F(KW)}{RPM\times RPM/Sec.} \quad (1)$$

where

WR^2 = effective inertia at the motor shaft including that of motor rotor
P_F = power required to overcome the friction in the motor and load when running at a constant speed (rpm)
RPM = the motor speed at which P_F is measured
$RPM/Sec.$ = the initial rate of retardation of the motor when the driving power is removed

When running the load test, data were obtained which, together with information furnished by Westinghouse Electric Corporation, enabled us to calculate, by means of equation 1 the effective WR^2 of the load as 15,900 pound-feet^2. The details of this calculation may be found with the derivation of equation 1.

The result obtained by the experimental method is 1,000 pound-feet^2 larger than that obtained by measurement. The difference is caused by the flywheel spokes and the gears of the system which were not considered in measurement. In future calculations, the effective inertia of the load will be taken as 15,900 pound-feet^2. Also, the motor rotor and flywheel will be considered as rigidly coupled; that is, they accelerate and decelerate simultaneously.

Flywheel Effect of the Load

Before the proper slip of the motor could be selected, it was first necessary to calculate the effect of the flywheel; that is, the power it generates when the motor slows down. A formula to calculate this power was derived as follows:

The kinetic energy absorbed or released by a flywheel during acceleration or deceleration can be calculated by the following formula:

$$KE = {}^1/_2 I(W_1^2 - W_2^2) \quad (2)$$

where

KE = kinetic energy, foot-pounds
I = inertia of flywheel, slug feet^2
W_1 = initial angular velocity of the flywheel, radians/second
W_2 = final angular velocity of the flywheel, radians/second

The units of inertia and angular velocity may be changed as follows.

1 slug = 32.16 pounds
1 rpm = $2\pi/60$ radians/second
1 radian/second = 30π rpm

Figure 3. Load test of present motor rolling two slabs

Multiplying factor = 400 kw

Applying these changes,

$$KE(\text{foot-pounds}) = 1.706\times10^{-4}\times WR^2\times(RPM_1^2 - RPM_2^2) \quad (3)$$

If the flywheel reaches its minimum speed in t seconds, the power generated during this period is

$$P(\text{foot-pounds/second}) = 1.706\times10^{-4}\times\frac{WR^2(RPM_1^2 - RPM_2^2)}{t} \quad (4)$$

Since

$1\ HP = 550$ foot-pounds/second

the power generated is

$$HP = 3.102\times10^{-7}\,\frac{WR^2(RPM_1^2 - RPM_2^2)}{t} \quad (5)$$

This formula represents the *average* horsepower developed by the flywheel during the deceleration period. While the instantaneous horsepower will vary considerably during the load peak, the average value is useful to determine the relative effect of the flywheel by comparing with the peak motor load.

To apply the foregoing formula to the rolling mill, the following measurements were made:

Speed of the motor before rolling = 600 rpm
Minimum speed of flywheel during rolling operation (two slabs) = 570 rpm
Time interval required to reach the lowest speed = approximately $2^1/_2$ seconds

The average power generated by the flywheel then is calculated from equation 5 as follows:

$$HP = 3.102\times10^{-7}\,\frac{15{,}900(600^2 - 570^2)}{2.5}$$
$$= 70$$

From the load curve, it is seen that the peak input to the motor when rolling two slabs is approximately 300 kw, which represents about 325 horsepower. The 70 horsepower contributed by the flywheel is 22 per cent of the peak, a very considerable percentage. However, this alone does not tell the complete story. It is necessary to compare the relative energy contributions of the flywheel and the motor. The energy contribution of the flywheel is calculated from equation 3, as follows:

$$KE = 1.706\times10^{-4}\times15{,}900(600^2 - 570^2)$$
$$= 95{,}000 \text{ foot-pounds}$$
$$= 173 \text{ horsepower-seconds}$$

The energy contributed by the motor may be calculated by measuring the area under the motor power curve (Figure 3) in kilowatt-seconds and then converting it to foot-pounds. This was done with a

Figure 4. Schematic cross section of flywheel

planimeter and the following results obtained:

Area under power curve:

$A_P = 2.35$ square inches (average)

Area under a chart section 400 kw high by 3.75 seconds wide (1,500 kilowatt-seconds):

$A_{cs} = 3.45$ square inches

Energy absorbed by motor during the load peak:

$$E = \frac{2.35}{3.45}\times1{,}500$$
$$= 1{,}020 \text{ kilowatt-seconds}$$

Assuming 70-per-cent over-all motor efficiency, the power contributed by the motor is

$$P = 0.70\times1{,}020$$
$$= 714 \text{ kilowatt-seconds}$$
$$= 0.198 \text{ kilowatt-hour}$$
$$1 \text{ kilowatt-hour} = 2.656\times10^6 \text{ foot-pounds}$$
$$P = 0.198\times2.656\times10^6$$
$$= 526{,}000 \text{ foot-pounds}$$

The energy contributed by the flywheel (95,000 foot-pounds) is then about 18 per cent of the energy delivered by the motor.

Discussion of Motor Characteristics

After the described tests and calculations had been made, it was felt that some consideration of basic principles would help in making an intelligent choice between the low-slip and the high-slip motors. In rolling and punch press applications having a flywheel, the high-slip motor usually is used for the following reasons:

1. Fuller utilization is made of the flywheel since it is given a chance to release more of its kinetic energy when the motor speed decreases during the load peak. This reduces the peak horsepower required of the motor and therefore the rms horsepower and horsepower rating (this will be explained more fully later). It should be remembered that the energy released by the flywheel is restored to it when the motor speeds up again, so that regardless of which type of motor is used, the total energy delivered by the motor remains unchanged. Also, it should be noted that the flywheel has expended its usefulness when the torque of the motor becomes equal to that of the load and the motor speed becomes constant.

2. The gears between the motor and the flywheel need not be designed to carry as great a peak load since more of the power required will be contributed by the flywheel. This often results in a considerable saving when designing a new piece of equipment.

3. The peak current will be reduced, thus reducing the voltage drop and lamp flicker. In new installations, smaller peak currents mean a reduction in feeder size.

Upon measuring the motor speed with a hand tachometer, it was found to be substantially constant over the middle portion of the rolling period. During this period, the flywheel has very little effect and the motor carries most of the load itself. In other words, the motor torque is almost equal to the load torque and the flywheel contribution is very small. From the previously calculated percentages of the horsepower and energy contributed by the flywheel, it is possible to construct the approximate horsepower–time curves (Figure 5) for the power required to roll two slabs (slab load), the power contributed by the motor (motor load), and the power contributed by the flywheel (flywheel power). The friction power is neglected. Upon inspection of these curves, the following points should be noted:

1. At every point the slab load is equal to the motor load plus the flywheel power. Negative values of flywheel power mean that the flywheel is absorbing energy and accelerating.

2. The energy contributed by the flywheel is equal to the energy absorbed by the flywheel. This must be true because the speed of the flywheel before and after the rolling cycle, and therefore its energy content, are the same.

3. The area under the slab load curve equals the area under the motor load curve, which means that the energy required by

Figure 5. Horsepower–time curves using low-slip motor

Energy contributed by flywheel is about 18 to 20 per cent of motor load

the slab equals the energy supplied by the motor. Neglecting the friction of the system, as we have been doing, this merely follows the law of conservation of energy since the flywheel neither absorbs or contributes energy over a complete cycle.

4. The energy contributed by the flywheel is about 18 to 20 per cent of the motor load (see the preceding text).

5. The motor load continues for about a second after the slab leaves the rolls. Also the peak in this curve lags behind the maximum of the slab load. Both of these phenomena are effects of the flywheel and are caused by the motor trying to restore to it the energy lost during deceleration. The flexibility of the couplings and the rate at which the slab load rises and falls also effect the shape of the curve.

6. From two to three seconds after rolling starts, the power contribution of the flywheel is very small and the motor must carry most of the load itself. Therefore, with a motor having $3^1/_2$ per cent slip at full load, the flywheel does very little toward reducing the load peak.

In view of this point, the next question that comes to mind is—"What will be the effect of a high-slip motor on the load curve?"

The effect of the high-slip motor on the load curves is shown in Figure 6. This motor would have a full load speed of about 560 rpm (seven per cent slip). Comparing the curves with those obtained using a low-slip motor, the following is noted:

1. The maximum horsepower developed by the flywheel, as well as its energy contribution, is considerably greater. As the high-slip motor will slow down at least twice as much as the low-slip motor, it will contribute at least twice as much energy to the load and, consequently, the energy contributed by the flywheel will be about 36 to 40 per cent of the motor load. The flywheel, therefore, reduces the peak of the motor load and also the pullout horsepower required of the motor.

2. The duration of the motor load is considerably longer because more energy must be restored to the flywheel and a considerable percentage of this energy cannot be restored until after the slab leaves the rolls and the motor gets a chance to speed up.

3. The duration of the slab load will be slightly longer and its maximum value slightly lower because the high-slip motor will operate at a slightly slower speed. As the difference in each case is only about five per cent, this does not represent any serious decrease in production.

4. By a similar line of reasoning as already presented in this paper, the energy contributed by the flywheel is equal to the energy absorbed by the flywheel, and also the area under the slab load curve is equal to the area under the motor load curve. Because the energy required by the slab will be the same regardless of the type of motor used, the areas under the slab load curves and, consequently, the areas under

Figure 6. Horsepower-time curves using high-slip motor

Energy contributed by flywheel is about 36 to 40 per cent of motor load

the motor load curves will be equal. (That is, all four areas are equal.)

The effect of the high-slip motor cannot be fully appreciated until its continuous load curve is compared to that obtained with the low-slip motor (Figure 3). To make this comparison, such a load curve is approximated in Figure 7. It is important to note that the curve is much smoother and that it has a lower peak. Also, the areas under both curves for the same number of slabs are equal, and, as the time will vary but a few per cent, the average values will be the same.

Motor Specifications

In order to compare the costs of the high-slip and low-slip motors, it was necessary to determine the complete motor specifications for each case, the horsepower rating, pullout torque, and slip being the most important. The other specifications—synchronous speed, time rating, voltage, frequency—are fixed, while the starting torque is relatively unimportant.

Figure 7. Expected load curve of high-slip motor

Compare with Figure 3—note smoother curve and lower peaks

The motor specifications were determined and outlined as follows.

Low Slip

First, the horsepower rating of the motor, which is equal to the rms of the load curve, must be fixed. Rms horsepower can be approximated as follows:

The rms value is defined briefly as "the square root of the average of the squares." To apply this method, divide the load curve into eight sections, as shown in Figure 3. (Eight sections are chosen for convenience. The accuracy of this method, as well as the result obtained, increases with the number of sections.) To find the rms ordinate of the curve the following formula is used:

$$\text{Rms ordinate} = \sqrt{\frac{(A_1)^2+(A_2)^2+\ldots(A_8)^2}{8}}$$

where A_1, A_2, ...A_8 are the average ordinates for each section. Applying this formula to Figure 3,

$$\text{Rms ordinate} = \sqrt{\frac{(0.07)^2+(0.28)^2+(0.57)^2+(0.75)^2+(0.75)^2+(0.72)^2+(0.64)^2+(0.28)^2}{8}} = 0.56$$

Assuming 70-per-cent over-all motor efficiency,

$$\text{Rms horsepower} = 0.56 \times 400 \times 1.341 \times 0.70 = 210$$

It was considered safe to use a 200-horsepower motor because the mill is idle for short periods of time when the slabs are transported from the receiving to the feeding end, rolls adjusted, waiting for slabs, and so forth.

Secondly, it is necessary to determine the pullout horsepower required of the motor. The maximum power required was approximately 325 horsepower. Since the standard low-slip NEMA class *A* motor usually has a pullout torque of about 250 per cent full load torque, the pullout horsepower of such a motor will be about 425 horsepower (assuming 15 per cent pullout slip) and will be capable of easily carrying the peak load.

Thirdly, the slip of the motor will be specified at approximately $3^1/_2$ per cent.

The complete motor specifications are therefore 200 horsepower, 580 rpm, continuous duty, open type, 40 degree-centigrade temperature rise, pullout torque not less than 250 per cent full load torque, 2,200 volts, 3 phase, 60 cycles.

High Slip

To determine the horsepower rating of the high-slip motor, it was decided to cal-

culate the rms horsepower of the motor load curve of Figure 6. To check the accuracy of this method, the rms horsepower for the low-slip motor was calculated from the motor load curve of Figure 5 and compared with the value obtained from Figure 3. For this purpose, both motor load curves were drawn separately and divided into eight sections each (Figure 8). The rms ordinates were calculated as already explained and found to be as follows:

High-slip motor—159 horsepower
Low-slip motor—211 horsepower

As the value obtained for the low-slip motor (211 horsepower) checked very well from that calculated from Figure 3 (210 horsepower), it was decided that the value of 159 horsepower obtained for the high-slip motor was sufficiently accurate and that the rating of the motor would be 150 horsepower.

The next step was to check whether or not the pullout torque was sufficient. The average power developed by the flywheel using a low-slip ($3^1/_2$ per cent) motor was 70 horsepower and the peak load was 325 horsepower. Using a high-slip (7 per cent) motor, it was considered safe to assume that this peak would be reduced 75 to 250 horsepower (see Figure 6). The pullout torque of a NEMA class *D* motor is usually 300 to 400 per cent full load torque. Assuming a 30-per-cent pullout slip, the pullout power at 350 per cent pullout torque is 368 horsepower, which is quite safe on an expected peak of 250 horsepower.

It should be remembered that the energy required to roll a certain number of slabs is the same, regardless of the type of motor used, and that the energy contributed by the flywheel in the first half of each cycle is restored to it during the

Figure 8. Calculation of rms horsepower from approximate horsepower–time curves

last half. This means that the areas under both motor load curves are the same and that the average horsepowers developed by both motors are essentially the same. The rms horsepower (and therefore the horsepower rating) of the high-slip motor is lower *only because it reduces the magnitude of the load peak.*

The complete motor specifications are 150 horsepower, 560 rpm, continuous duty, open type, 40-degree-centigrade temperature rise, pullout torque not less than 350 per cent full load torque, 2,200 volts, 3 phase, 60 cycles.

Conclusion

Before making the final selection, it is considered advisable to review the three main reasons for using a high-slip motor.

1. Fuller utilization of the flywheel to reduce rms horsepower.
2. Reduction in size of gears between the motor and flywheel.
3. Reduction in peak currents, size of feeders, and sometimes, transformers.

Reduction of rms horsepower may mean a reduction in cost and size of the motor. Reduction in size of gears, feeders, and transformers usually is reflected in a considerable saving.

Investigation of the two remaining possibilities revealed that a 150-horsepower high-slip motor would cost about 15 per cent more and would be larger than a 200-horsepower low-slip motor. In a new installation, the explained savings would more than offset the additional cost of the motor, and the decision unquestionably would be in favor of a high-slip motor. It can be seen, however, that since the gears already were built and the feeders and transformers installed, neither of the three reasons mentioned are applicable in this case. In view of these considerations, and, also, the fact that delivery on the high-slip motor was quoted as twice that of the low-slip motor, it was decided to use a low-slip motor.

It is believed that the methods and calculations explained in this paper can be adapted to many different types of applications involving both new and existing installations. It is a fact well accepted by engineers that time spent in determining, as accurately as possible, the motor size required by a given application is well worth while. Excess horsepower on any induction motor drive is expensive in first cost of motor and control and often entails an additional expense of power-factor correction.

Discussion

Fraser Jeffrey (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): In considering power requirements for intermittent loading with peak conditions occurring at frequent intervals, it is well to work with equivalent horsepower corresponding to rms values of kilovolt-amperes rather than rms values of power directly. This is because the power factor and the efficiency of both synchronous and induction motors vary widely with the load, size, and speed, and the current or kilovolt-amperes will not be proportional to the load.

Thus, the equivalent horsepower rating of a unity power factor synchronous motor necessary to handle a certain highly fluctuating load will be different from the equivalent horsepower rating of an 80-per-cent-power-factor synchronous motor necessary to handle the same load. The same statement is true, although the difference may be less pronounced, when comparing induction motors having different power factor and efficiency curves.

To determine the value of kilovolt-amperes which will give the same average heating as the actual variable kilovolt-ampere input to the motor, the resultant rms kilovolt-amperes will be

$$0.746\sqrt{\frac{\left(\frac{P_1}{\cos\phi_1\eta_1}\right)^2 t_1+\left(\frac{P_2}{\cos\phi_2\eta_2}\right)^2 t_2+\ldots\left(\frac{P_n}{\cos\phi_n\eta_n}\right)^2 t_n}{t_1+t_2+\ldots t_n}} \qquad (1)$$

where

$P_1, P_2 \ldots P_n$ = average load in horsepower for each ordinate section
$t_1, t_2 \ldots t_n$ = time interval of the various ordinates in minutes
$\cos\phi_1, \cos\phi_2 \ldots \cos\phi_n$ = power factor of motor at power loads $P_1, P_2 \ldots P_n$
$\cos\phi$ = full load rated power factor of motor
$\eta_1, \eta_2 \ldots \eta_n$ = efficiency of motor at power loads $P_1, P_2 \ldots P_n$
η = full load efficiency of motor

The equivalent horsepower rating of a motor corresponding to the rms kilovolt-amperes input as per equation 1, that is, the horsepower rating of a motor which, if operated continuously at full load, would show the same average heating as it would

if operated on the load cycle in question, then will be

Equivalent horsepower =

rms kilovolts-amperes from equation 1 $\times \dfrac{\cos\phi \times \eta}{0.746}$ (2)

$$= \cos\phi \times \eta \sqrt{\frac{\left(\frac{P_1}{\cos\phi_1\eta_1}\right)^2 t_1 + \left(\frac{P_2}{\cos\phi_2\eta_2}\right)^2 t_2 + \ldots \left(\frac{P_n}{\cos\phi_n\eta_n}\right)^2 t_n}{t_1 + t_2 + \ldots t_n}} \quad (3)$$

This method of approach may show quite large differences in motor capacities required when the application of different types and different speeds of a-c motors is under consideration.

L. A. Umansky (General Electric Company, Schenectady, N. Y.): The problem of dividing the rolling mill load between the motors and flywheels has been well covered in the literature. The fundamental equations were outlined by Gasche in 1910 before this Institute.[1]

Assuming a rectangular load curve (see Figure 1 of this discussion), with T_1 being the total rolling torque (in pound-feet) and T_0 the initial value of motor torque (when $t=0$), T, the motor torque at any time t (t in seconds, after the beginning of rolling, or after the beginning of interval between passes), may be expressed as

$$T = T_1 - \frac{T_1 - T_0}{e^{At}} \quad (1)$$

and

$$A = \frac{308 T_n}{Wk^2 \times N_s \times S_n} \quad (2)$$

Where

T_n = motor rated torque, in pound-feet
S_n = motor rated slip, in fractions
N_s = synchronous speed in revolutions per minute
Wk^2 = total flywheel effect of rotating parts, in pound-feet^2, referred to motor shaft

If the total load curve is not rectangular but trapezoidal in shape, a somewhat more involved expression can be written readily.

The difference between the total load torque (T_1) and the motor torque (T) is supplied by the flywheel which slows down during the rolling pass and thereby releases a portion of its stored energy. Likewise, during the interval between the passes the excess of motor torque (T') over the friction torque (T_1') goes to accelerate the flywheel.

It is clear that the maximum motor load exists at point B, that is, at the end of the rolling pass. As soon as the metal leaves the rolls, the motor load inevitably goes down. In this respect Figures 5 and 6 of Berkley's paper may be questioned; the motor load is shown as still increasing after its curved crosses the curve of the slab load.

Figure 1

REFERENCE

1. INTERACTION OF FLYWHEELS AND MOTORS WHEN DRIVING ROLL TRAINS BY INDUCTION MOTORS, F. G. Gasche. AIEE TRANSACTIONS, volume 29, part 2, 1910, pages 1385–1402.

J. S. Gault (University of Michigan, Ann Arbor, Mich.): In the analysis of motor and flywheel behavior shown in Figure 5 of the paper, the peak motor load is shown to occur after the rolling is practically finished and about one-half second after the flywheel power has reversed. This is not possible. If the flywheel is absorbing energy, the speed must be increasing, and the motor input power will be decreasing.

The motor peak will come later than the peak rolling load, as stated by Berkley but cannot occur after the slab has left the rolls. The motor peak will be at the point where the flywheel power changes sign, at about 2.5 seconds.

Similarly, in the predicted curves of Figure 6 of the paper, the motor peak should be shown at three seconds instead of 3.7 seconds approximately.

Another point on which there is some question is his dismissal of possibility number 3, the wound rotor induction motor, on the grounds that it was too expensive. This possibility really deserves more consideration. It has all the same advantages shown for the high slip motor, and furthermore, because the rotor losses are not dissipated in the machine, it does not have to be built in an oversize frame. It would seem also that the ability to change speed might be somewhat more valuable in this application than the paper would indicate.

L. H. Berkley: The method of approach, outlined by Fraser Jeffrey, is very valuable and undoubtedly will give a more accurate result. A slight variation of his formula also can be used to advantage in calculating the rms horsepower from Figure 3 of the paper.

Gault is correct in stating that the peak motor load cannot occur after the flywheel power has reversed. As the motor load increases, the motor speed drops, and the flywheel power is positive; when the motor load decreases, the motor speed increases, and the flywheel power becomes negative. Thus, the flywheel power will reverse at the peak motor load.

Also, as stated by L. A. Umansky, the motor load curve cannot increase after it crosses the slab load curve, because the difference in the two curves indicates that the flywheel is gaining energy and the motor speed is increasing. This can occur only when the motor load is decreasing.

An Extension of Impact Speed-Drop Analysis

F. E. CREVER
MEMBER AIEE

WHEN a sudden load change occurs on a d-c motor operating at a given flux there is a transient speed change as a result. Formulas have been available which allow calculation of the transient speed change for a number of years. These formulas do not, however, give as clear a picture of the effect of varying certain factors as might be desired. Also considerable labor is involved in calculating the transient speed change for a given set of values of the determining factors.

It is the object of this study to extend the analysis so that the calculations may be made easily. It is a further object to plot the effect on impact speed drop of varying certain determining factors.

Method of Analysis

The transient speed change is obtained by solution of two differential equations. One is a voltage equation and the other a torque equation. The resulting formula for speed change has been given in other papers but is repeated in the appendix of this paper in order to have all of the information together. From the appendix we take the solution for the case when a damped oscillation is encountered,

$$S=S_o-\frac{\Delta TR}{K_eK_t}\left[1+\frac{1}{\omega t_s}\,\epsilon^{-\alpha t}\cos\,(\omega t+\delta)\right] \quad (1)$$

S = the speed at any time after sudden load change
S_o = the initial speed
ΔT = the suddenly applied torque
R = the motor-armature-circuit resistance
K_e = the motor counter electromotive force per revolution per minute
K_t = the motor torque per ampere
ω = the angular velocity of oscillation

$$t_s=\frac{2\pi}{60}\times\frac{WK^2}{32.2}\times\frac{R}{K_eK_t}$$

= speed time constant
α = the damping factor

$$=\frac{1}{2t_t}$$

$\delta=\cos^{-1}(-\omega t_s)$
t = time in seconds after the load change
$t_t=\frac{L}{R}$ of motor-armature circuit

The general form of the speed change given by equation 1 above is shown in Figure 1*A*. In this illustration are shown also the following factors:

d = the impact speed drop
s = the steady-state speed drop
$d-s$ = the undershoot of steady-state speed on the first downward swing
O_r = the overshoot of the final speed on the first recovery
t_d = the time to reach impact speed drop
t_o = the time to pass through the steady-state speed on the first downward swing
t_r = the time to reach the peak of the first overswing

All of these factors can be obtained by substituting particular values into equation 1 and plotting the speed-time curve.

The impact speed drop d also can be obtained by differentiating equation 1 and equating ds/dt to zero and solving for t_d. Substitution of this value of time into equation 1 will give d the impact speed drop. In this manner we obtain the following relationships

$$\cos\,\omega t_d+\delta=-\sqrt{\frac{\omega^2}{\alpha^2+\omega^2}} \quad (2)$$

$$t_d=\frac{\cos^{-1}-\sqrt{\frac{\omega^2}{\alpha^2+\omega^2}}-\cos^{-1}-\omega t_s}{\omega} \quad (3)$$

$$d=-\frac{\Delta TR}{K_eK_t}\,\epsilon^{-\frac{\alpha}{\omega}\left(\cos^{-1}\sqrt{\frac{\omega^2}{\alpha^2+\omega^2}}-\cos^{-1}\omega t_s\right)}\times\sqrt{\frac{\omega^2}{\alpha^2+\omega^2}} \quad (4)$$

Let us now confine our attention to equation 1 and examine each term so as to see of what each is a function.

Equation 1 can be put in the following form

$$S-S_o=-\frac{\Delta TR}{K_eK_t}\left[1+\frac{1}{\omega t_s}\,\epsilon^{-\alpha t}\cos\,(\omega t+\delta)\right]$$

$S-S_o=\Delta S$ the speed change

$\frac{\Delta T}{K_t}$ = current in the armature required to develop a torque equal to the suddenly applied torque

$\frac{\Delta TR}{K_t}$ = voltage drop resulting from resistance of armature times current required to develop applied torque

$\frac{\Delta TR}{K_eK_t}$ = revolutions per minute change resulting from voltage drop in resistance of armature circuit

This latter factor in per cent of the initial speed is the same as the per cent *IR* drop with respect to the armature applied voltage.

$$\frac{1}{\omega t_s}=2\sqrt{\frac{\frac{t}{t_s}}{4-\frac{t_s}{t_t}}}$$

= a function of $\frac{t_t}{t_s}$ only

$\alpha t=\frac{t}{2t_t}$ This is a function of t and t_t, but if we consider the time t in multiples of one cycle of oscillation the term becomes a function of $\frac{t_t}{t_s}$ only

Paper 47-29, recommended by the AIEE committee on industrial power applications and electric machinery for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted November 18, 1946; made available for printing December 20, 1946.

F. E. CREVER is with the general engineering and consulting laboratory, General Electric Company, Schenectady, N. Y. He was formerly with the steel mill division of the industrial engineering divisions.

Figure 1*A* (above). General form of impact speed drop with suddenly applied load

Figure 1*B* (left). Impact speed drop as a function of time constant ratio

Figure 1*C* (below). Impact speed drop as a function of time constant ratio to extended scale

IMPACT SPEED DROP CURVES

$\delta = \cos^{-1}(-\omega t_s)$

$= \cos^{-1}\sqrt{\frac{t_2}{t_1} - \frac{t_2^2}{4t_1^2}}$ which is a function of $\frac{t_1}{t_2}$ only

ωt is a function of t_1, $\frac{t_1}{t_2}$, and t, but again as in the case of ωt if time is expressed in terms of multiples of the time for one cycle of oscillation the term becomes a function of $\frac{t_1}{t_2}$ only

From this examination we reach the important conclusion that the form of the speed change on impact loading is a function of t_1/t_2 only.

The applied torque and the resistance determine the magnitude as a simple multiplying factor. The values of t_2 and t_1 merely change the time scale and do not alter the form so long as their ratio remains fixed.

Therefore we can calculate the form once for all ratios of t_1/t_2 encountered in practice and plot the values against t_1/t_2.

Now let us concentrate our attention in equation 4 on d the impact speed drop. We again have the same multiplying factor $-\Delta TR/K_eK_t$. The remaining factors are all functions of t_1/t_2 only, which is necessarily so if our conclusions reached from examination of equation 1 are correct. The factors in terms of the ratio of t_1/t_2 are as follows:

$$-\frac{\alpha}{\omega} = \frac{-1}{\sqrt{\frac{4t_1}{t_2} - 1}}$$

$$\sqrt{\frac{\omega^2}{\alpha^2\omega^2}} = \sqrt{\frac{4t_1}{t_2} - 1}$$

$$-\omega t_s = -\sqrt{\frac{t_2}{t_1} - \frac{t_2^2}{4t_1^2}}$$

Therefore, d in terms of multiples of the IR drop is a function of t_1/t_2 only and is plotted so in Figures 1*B* and 1*C*.

The angular velocity ω, the frequency f, and the time for one cycle of oscillation are functions of both t_1/t_2 and the value of t_1 as well.

Therefore, these values are given in Figure 2 as nomographs.

The time t_d to reach impact speed drop is a function of both t_1/t_2 and t_1 and is given in the form of a nomograph in Figures 3*A* and 3*B*. ωt_d is a function of t_1/t_2 only and is plotted in Figure 4.

The time to pass through the steady-state speed on the first downward swing is a function of both t_1/t_2 and t_1, but ωt_o is a function of t_1/t_2 only and is plotted in Figure 5.

The ratio of successive maximum amplitudes of oscillation about the final speed on successive half cycles is $\epsilon^{-\frac{\alpha}{\omega}\pi}$ and is a function of t_1/t_2 only. It is plotted in Figures 6*A* and 6*B*.

The value $(d-s)$ is the underswing of the steady-state speed on the first downward swing and O_f is the overshoot on the next recovery. These are plotted in Figures 7*A* and 7*B* as functions of t_1/t_2.

Explanation of Charts and How to Use Them

To use the charts obtain the following motor data:

Armature-circuit resistance = R ohms

Armature-circuit inductance $=L$ henrys
Motor WK^2 in pound-feet^2. (Include WK^2 of load if any)
Motor speed in revolutions per minute (operating speed)
Motor voltage and rated current V_r and I_r

Then figure the ratio of t_i to t_s from the following formulas:

$$K_s=\frac{\text{volts}}{\text{revolutions per minute}}$$

$$t_i=\frac{L}{R}$$

$$t_s=\frac{2\pi}{60}\frac{WK^2}{32.2}\times\frac{R}{7.05\,K_s^2}$$

$$t_s=0.000461\frac{WK^2R}{K_s^2}$$

The per cent resistance drop of the motor $=I_R=R\times100/V_R$ for rated current or torque.

Impact Speed Drop d

In either Figure 1*B* or 1*C* look up d, the impact speed drop corresponding to the value of t_i/t_s of the motor.

Multiply this value by the per cent resistance drop of the current corresponding to the applied torque, namely,

$$\frac{IR}{V_o}\times100\,\frac{V_r}{V_o}\,\frac{\Delta T}{T_r}\times\text{per cent resistance drop at rated load}$$

where

V_o = operating voltage
V_r = rated voltage
T_r = rated torque
T = suddenly applied torque

This gives the impact speed drop in per cent of the operating speed before impact loading.

Time to Reach Impact Speed Drop

The time t_d to reach the impact speed drop may be obtained in either of two ways depending upon the accuracy required.

For a quick check, obtain ω from Figure 2 by reading the point of intersection on the center scale of a straight line connecting t_i and t_i/t_s on the outer scales.

(The value of f, the frequency of oscillation, also may be read from Figure 2.) The time for one cycle is $1/f$.

Use the value of ω obtained from Figure 2 on Figures 3*A* and 3*B* by laying a straight line between the proper values of t_i/t_s and ω and read t_d in seconds on the right-hand scale.

For higher accuracy look up ω in Figures 3*A* and 3*B* as before and look up t_d in Figure 4. Divide ωt_d by ω to obtain t_d.

Figure 2. Nomograph of frequency of oscillation as a function of time constant ratio and value

To Draw Complete Speed–Time Curve

Complete the calculations and note the time for one cycle. Successive overswings of the final steady-state speed are in fixed ratio depending upon the value of t_i/t_s as plotted in Figures 6*A* and 6*B*.

Figures 7*A* and 7*B* show both $(d-s)$ and O_r, the first overshoot, in multiples of the per cent resistance drop.

Note that the times of crossing the final steady-state speed value are not spaced halfway between the times at which maximum overswing occurs.

To obtain t_o look up the value of ωt_o (Figure 5) that corresponds to the value of t_i/t_s in question. Divide ωt_o by ω to obtain t_o. Successive time values of crossing the steady-state speed value are obtained by adding the time for one-half cycle to t_o.

Successive values of time at the peaks of the swings are obtained by adding the time for one-half cycle to t_d; thus $t_r=t_d$ plus the time for one-half cycle as shown in Figure 1*A*.

Example of Use of Charts

Consider a motor with pole-face winding rated 8 pole, 1,000 horsepower, 600 volt, 225/730 rpm with the following constants:

$R=0.0180$ ohm
$L=0.0007$ henry
$WK^2=32{,}100$ pound-feet^2
total $WK^2=34{,}300$
load $WK^2=2{,}200$ pound-feet^2

At 225 rpm 600 volts suddenly apply 90 per cent full-load torque.

$$K_s=\frac{600}{225}$$
$$=2.67 \text{ volts per revolution per minute}$$

$$t_i=\frac{0.00072}{0.0180}$$
$$=0.040 \text{ second}$$

$$t_s=\frac{0.000461\times34{,}300\times0.0180}{2.67^2}$$
$$=0.04 \text{ second}$$

Figure 3A. Nomograph of time to reach impact speed drop

Figure 3B. Nomograph of time to reach impact speed drop

$I_r = 1{,}310$ amperes

$$\frac{I_r R}{V_r} \times 100 = \frac{1{,}310 \times 0.0180}{600}$$
$$= 3.93 \text{ per cent}$$

$$\frac{t_l}{t_s} = \frac{0.04}{0.04}$$
$$= 1.0$$

From Figure 1*C* for $t_l/t_s = 1$, d is 1.3 times the per cent resistance drop. As we are applying 90 per cent load d will be

$0.9 \times 1.3 \times 3.93 = 4.59$ per cent of initial speed

From Figure 2,

$\omega = 21.6$ radians per second
$f = 3.44$ cycles per second
Time for one cycle $= 0.29$ second

From Figure 3*A*,

$t_d = 0.097$ second

Successive peaks occur at

$$\left(0.097 + \frac{0.29}{2} = 0.242\right)$$
$$(0.097 + 0.29 = 0.387)$$

and so forth. From Figure 5

$\omega t_o = 1.05$ seconds

$$t_o = \frac{1.05}{21.6}$$
$$= 0.0486 \text{ second}$$

Successive crossings of the final speed value occur at

$$0.0486 + \frac{0.29}{2} = 0.1936$$

$$0.0486 + 0.29 = 0.338$$

and so forth. From Figure 6*B*, the ratio of the overswing on successive half cycles is 0.164.

The steady-state speed drop is

$0.9 \times 3.93 = 3.54$ per cent

The value of the first underswing below the final speed is

$$d - 3.54 = 4.59 - 3.54$$
$$= 1.05 \text{ per cent}$$

The overshoot of final speed on the first upswing is 1.05×0.164 or 0.172 per cent. The speed at this point will be $3.54 - 0.17 = 3.37$ per cent below the initial speed.

If the first overswing is all that is required the value could have been obtained from Figure 7*B*.

Conclusions

1. The charts give a simple and quick means of drawing the speed change upon impact loading.

2. They also show that both low resistance and low inductance are important to obtain low impact speed drop.

3. While it is theoretically necessary to make $t_s = 4t_l$ giving a ratio of t_l/t_s of 0.25 for nonoscillatory response, the curves show that the response with $t_s = 3t_l$, that is, t_l/t_s 0.333 is so very close to nonoscillatory that it is unnecessary to use any greater value of WK^2 at base speed.

4. The charts should form a basis for a definition of a low impact speed-drop motor when considered in conjunction with motor design data.

Appendix

Let

V = applied armature voltage
K_e = motor counter electromotive force per revolutions per minute
S = motor speed in revolutions per minute
ΔS = motor speed change in revolutions per minute
R = motor-armature-circuit resistance
L = motor-armature-circuit inductance
i = motor-armature current
p = differential operator with respect to time
K_t = motor torque per ampere
T_o = initial load torque
T = applied torque
1 = unit function

$$M = \frac{2\pi}{60} \times \frac{WK^2}{32.2}$$

Assuming the counter electromotive force of the motor per revolutions per minute to be constant, the equations whose simultaneous solution give the transient change in motor

Figure 4. Chart showing product of natural angular velocity and time to reach impact speed drop as a function of time constant ratio

Figure 5 (above, right). Chart showing product of natural angular velocity and time to reach final speed on first downward swing

speed upon suddenly applied load are as follows:

1. By summation of voltages in motor-armature circuit

$$V-K_eS=R_i+Lpi$$

2. By summation of torques on the motor shaft

$$K_ti=T_0+T1+MpS$$

In order to simplify the analysis we may use Δ values to indicate changes and then superpose these on the initial conditions to obtain the complete solution.

The equations then become

$$\begin{aligned}-K_e\Delta S&=(R+Lp)\,\Delta i\\ K_t\Delta i&=+\Delta T1+Mp\,\Delta S\end{aligned}\qquad(5)$$

From equation 5

$$\Delta i=\frac{-K_e\Delta S}{(R+Lp)}\qquad(6)$$

Substituting this into equation 6 for Δi and solving for ΔS we obtain

$$\Delta S=\frac{-T1(R+L_p)}{M_p(R+L_p)+K_tK_e}$$

Divide numerator and denominator by R

$$\Delta S=\frac{-\Delta T1\left(1+\frac{Lp}{R}\right)}{\frac{ML_p^2}{R}+\frac{MR_p}{R}+\frac{K_eK_t}{R}}$$

$$=\frac{-\Delta T1\left(1+\frac{Lp}{R}\right)}{\frac{K_eK_t}{R}\left(\frac{MR}{K_eK_t}\times\frac{Lp^2}{R}+\frac{MR}{K_eK_t}\times P+1\right)}$$

If we let

$$t_t=\frac{L}{R}$$

=current time constant

$$\Delta S = \frac{-\Delta TR}{K_p K_t}\left(\frac{1+t_{1p}}{t_1 t_s P^2 + t_{sp} + 1}\right) 1$$

The roots of the denominator of the operational expression are

$$P_1 = -\frac{1}{2t_1} + \sqrt{\frac{1}{4t_1^2} - \frac{1}{t_1 t_s}}$$

$$P_2 = -\frac{1}{2t_1} - \sqrt{\frac{1}{4t_1^2} - \frac{1}{t_1 t_s}}$$

$$P_1 = -\alpha + \beta$$

$$P_2 = -\alpha - \beta$$

where

$$\alpha = \frac{1}{2t_1}$$

$$\beta = \sqrt{\frac{1}{4t_1^2} - \frac{1}{t_1 t_s}}$$

Evaluation of the operational expression takes on three forms as follows:

(a). When $t_s > 4t_1$ both roots are real and negative.

$$\Delta S = \frac{-\Delta TR}{K_p K_t}\left[1 + \frac{\frac{1}{2} + \sqrt{\frac{1}{4} - \frac{t_s}{t_s e}}}{\frac{1}{2}\frac{t_s}{t_1} - 2 - \sqrt{\frac{1}{4}\frac{t_s^2}{t_1^2} - \frac{t_s}{t_1}}} \cdot e^{(-\alpha+\beta)t} + \frac{\frac{1}{2} - \sqrt{\frac{1}{4} - \frac{t_1}{t_s}}}{\frac{1}{2}\frac{t_s}{t_1} - 2\sqrt{\frac{1}{4}\frac{t_s^2}{t_1^2} - \frac{t_s}{t_1}}} \cdot e^{(-\alpha+\beta)t}\right]$$

(b). When $t_s = 4t_1$ both roots are equal.

$$P_1 = P_2 = \frac{-1}{2t_1} = -\alpha$$

and the solution is

$$\Delta S = -\frac{\Delta TR}{K_p K_t}\left[1 - e^{-\alpha t} - \frac{\alpha t}{2} e^{-\alpha t}\right]$$

(c). When $t_s < 4t_1$ the roots are complex and the solution is

$$\Delta S = -\frac{\Delta TR}{K_p K_t}\left[1 + \frac{1}{\omega t_s} e^{-\alpha t} \cos(\omega t + \delta)\right]$$

In this latter case the equation for ΔS is a damped oscillation.

The speed $S = \Delta S + S_0$

or

$$S = S_0 - \frac{\Delta TR}{K_p K_t} \times \left[1 + \frac{1}{\omega t_s} e^{-\alpha t} \cos(\omega t + \delta)\right]$$

Cathodic Protection of Steel Water Tanks Using Aluminum Anodes

L. P. SUDRABIN
NONMEMBER AIEE

R. B. MEARS
NONMEMBER AIEE

Synopsis: Aluminum alloy anodes have been used in approximately 1,000 installations of cathodic protection of steel water tanks using current from an outside source. From fundamental considerations it would be expected that the loss in weight per ampere hour of current passed from aluminum anodes would be less than one-third the weight loss from steel anodes. This expectation is confirmed in service. In addition, it was found that the aluminum anodes developed a more uniform attack than did anodes of steel or stainless steel. This is desirable because localized attack can result in early anode failure. The corrosion products from the aluminum anodes are white or colorless and adhere to the anodes. In the case of anodes of many other metals the corrosion products are strongly colored and fall off the anodes, thus discoloring or otherwise contaminating the water. Anodes of several aluminum-base alloys all have proved satisfactory in field installations. However, anodes of the aluminum-copper alloys (such as 17*S-T* or 24*S-T*) appear to be superior to anodes of unalloyed aluminum (2*S*) or to aluminum-zinc alloy anodes.

CATHODIC PROTECTION can be obtained either by using direct current supplied by some external source, as by a motordriven generator, or by means of galvanic action resulting from contact with metal that is anodic to the metal to be protected. In this paper attention will be directed mainly to the first, or applied current, method of cathodic protection. In another paper[1] by one of the authors the use of galvanic anodes made of light metals for protecting steel structures was discussed, and in a series of papers[2] by the other author cathodic protection by external current using steel, cast iron, or carbon anodes has been described.

Paper 47-30, recommended by the AIEE committee on electrochemistry and electrometallurgy for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted March 3, 1946; made available for printing December 3, 1946.

L. P. SUDRABIN is a chemical engineer with Electro Rust-Proofing Corporation, Newark, N. J.; R. B. MEARS was formerly with Aluminum Company of America, New Kensington, Pa.

Aluminum has certain inherent advantages for use as anodes with applied current. Its most obvious one is its low electrochemical equivalent. This means that at 100 per cent anode current efficiency a smaller weight of aluminum will be dissolved per ampere-hour of current passed than is the case for any other appropriate metal. The metalloid carbon has a lower electrochemical equivalent than does aluminum. The electrochemical equivalents of several of the common metals and of carbon are given in Table I. From this table it will be noted that one pound of aluminum, theoretically, will supply over three times as many ampere-hours of current as one pound of iron. This means that an aluminum anode only one-third the weight of an iron anode should last longer than an iron anode under similar service conditions.

This lighter weight of equivalent aluminum anodes is important in reducing transportation and labor charges incidental to installation of the anodes. Where the anodes are to be used in elevated water tanks, the ease of handling the lighter aluminum anodes is of particular value.

From Table I, the use of anodes of carbon (or graphite) would appear interesting because of the high electrochemical equivalent. However, anodes of these materials have undesirable physical properties for such applications. In addition, service tests have indicated that such anodes disintegrate rapidly in many waters, probably as a result of attack of the binder followed by sloughing off of unattacked particles of carbon or graphite.

Other Advantages of Aluminum Anodes

Other desirable properties of anodes are that they must not form films of high resistance which would limit current flow. Also, they should corrode uniformly without the development of deep pits. Localized pitting attack can result in complete penetration of the anode and possibly even in corrosion in two before the main mass of the anode has been consumed. This results in great reduction in anode life. As is shown in the examples which are described subsequently, aluminum anodes have proved very satisfactory in both of these respects.

It is also frequently desirable that corrosion products from the anodes do not discolor the water. The corrosion products from aluminum anodes are white or colorless and are, therefore, not as objectionable as are the products from anodes of many other metals.

Application of Cathodic Protection

Since 1935 cathodic protection has been applied as a method of underwater corrosion control to over 4,000 industrial and municipal water storage tanks in the United States and Canada. These tanks range in capacity from only a few gallons to over six million gallons. A typical installation in a hemispherical-bottom elevated tank is illustrated in Figure 1.

Each anode is suspended vertically from a fixed structure such as the tank roof, by means of one-fourth-inch galvanized cable. A strain insulator is used to insulate the anode from the tank structure. The positive lead connection is made to the upper six inches of the electrode, which extends above the high water line.

The electrode is assembled into the re-

Figure 1. Typical cathodic installation in an elevated tank

Table I. Electrochemical Equivalents of Various Anode Materials

Anode Material	Weight of Material Consumed Per 26.8 Ampere-Hours of Current Passed, Grams	Ampere-Hours Per Pound of Material
Aluminum	9.0	1,552
Graphite	6.0 or 3.0	2,021 or 4,042
Copper	31.8	382
Iron	27.9	436
Lead	103.6	117
Magnesium	12.2	997
Nickel	29.3	416
Zinc	32.7	372

quired length by joining 12-foot long aluminum rod sections end on end with threaded couplings. All couplings are protected by rubber and friction tape. The electrode can be installed and replaced from the tank roof through a 4- or 6-inch-diameter hole cut in the roof adjacent to the point of electrode suspension. The hole cut through the roof is covered with a gasketed plate to prevent birds and debris from entering the tank.

In practice there is no pronounced attack occurring on the anode at the water level. The water level in tanks is rarely kept constant and this operational characteristic probably accounts for the absence of marked attack at the water surface.

However, special care must be given to the taping procedure used to protect the threaded coupling so as to prevent premature local failure of the anode. It has been observed that the longer the taped section on the anode, the greater is the metal wastage immediately adjacent to the tape.

Platinum anodes also have been used to some extent. These have the advantage that they are not attacked appreciably even after prolonged periods of service. However, they have several severe limitations.

1. Because of the high cost of platinum they generally are used in the form of wires of small diameter. This means that higher anode current densities must be used in order to provide equal current to the tank being protected. The higher current densities cause higher IR drops in the water, resulting in higher power costs.

2. Because the platinum is inert, the main anode reaction is the evolution of oxygen. When aluminum anodes are used, the main anode reaction is the dissolution of aluminum. The oxygen evolved from the platinum anode dissolves in the water and increases its corrosiveness. This means, in tanks confining water with a low dissolved oxygen concentration, that higher current densities are required to protect the walls of the water tank and also that steel equipment through which the water from the tank passes will have its corrosion accelerated because of the increased quantities of oxygen dissolved in it.

3. As fine wires of platinum are used there is a definite hazard that they will be broken or bent out of position by ice formation during cold weather.

Beginning in 1939, trial installations were started using aluminum anodes. The results of these trial installations were so promising that early in 1945 the use of aluminum anodes was generally adopted. At the present time aluminum anodes are being used in approximately 1,000 installations of cathodic protection. The results of some typical applications of aluminum anodes are summarized in the following paragraphs.

Example *A*—Two 75,000-Gallon Elevated Sprinkler Tanks

In August 1944 cathodic protection was applied to two 75,000-gallon hemispherical-bottom elevated tanks, which are used for sprinkler water storage at the American Suppliers, Inc. warehouse in Louisville, Ky. These tanks, being alike, lent themselves to study whereby the properties of certain electrode materials could be compared.

Each tank had a single electrode, supported from an insulator, along the vertical center axis of the tank. In one tank the electrode was of seven-eighths-inch-diameter hot-rolled SAE-1020 steel rod submerged for a distance of $21^1/_2$ feet below the high water level. In the other tank aluminum alloy rod (Alcoa 17*S*-*T**) having identical dimensions was used.

An average current flow of 1.60–1.62 amperes was projected from each electrode to the tank. The impressed voltage required to maintain this amperage ranged from 5.0 to 10.0 volts, depending upon variations in conductivity of the water. As the voltage requirements were alike in both tanks, it appears that aluminum does not possess marked electrical valving properties under the conditions of the application.

On February 20, 1945, after the removal of the degradation product, an examination of the aluminum alloy rod

* Composition and properties given in Table II.

Table II. Composition and Properties of Aluminum Alloys

Alloy	Composition	Temper	Typical Mechanical Properties: Tensile Strength, Pounds Per Square Inch	Elongation, Percentage in Two Inches
2*S*	Commercially pure aluminum containing at least 99 per cent aluminum	*O*	13,000	35
		H	24,000	5
72*S*	Aluminum alloy containing 1 per cent zinc	*O*	11,000	35
		H	20,000	5
17*S*	Aluminum alloy containing 4 per cent copper, 0.5 per cent manganese, 0.5 per cent magnesium	*O*	26,000	20
		T	62,000	20
24*S*	Aluminum alloy containing 4.5 per cent copper, 0.6 per cent manganese, 1.5 per cent magnesium	*O*	27,000	19
		T	68,000	19
Alclad 24*S*	This is a duplex product with a 2*S* coating on both sides of a 24*S* core	*O*	25,000	18
		T	64,000	18

Table III. Comparative Anode Performance in Elevated Sprinkler Tanks at Louisville, Ky.

Tank	Anode	Weight, Pounds	Service Hours	Ampere-Hours	Over-all Anode Efficiency, Per Cent
A	1/8-by-21 1/8-inch hot-rolled SAE-1020 steel	43.9	9,100	14,650	77
B	1/8-by-21 1/8-inch aluminum alloy 17*S-T*	15.6	10,600	17,050	81

revealed fairly uniform wastage. The hot-rolled SAE-1020 steel rod was grooved badly with three zones along the length of the rod where premature failure could occur because of localized wastage. This characteristic found in most steel electrodes, including the stainless steels, is especially undesirable since such a failure will result in improper current distribution after the electrode has been shortened.

A marked variation in amperage obtained in relation to applied voltage indicated the failure of the aluminum alloy rod on October 31, 1945. The hot-rolled SAE-1020 steel rod had failed some two months earlier. A performance comparison of 17*S-T* aluminum alloy and hot-rolled SAE-1020 steel rod is shown in Table III, while the composition of the water is given in Table IV. The tanks were kept full by replacing evaporation and leakage losses with Louisville, Ky. water at weekly intervals. Although the water used in filling the tank approaches saturation with dissolved oxygen, it is interesting to note the marked reduction of dissolved oxygen occurring in the water stored in this tank.

Table IV. Louisville, Ky. Water Analysis

Total dissolved solids	221 parts per million
Total hardness	115 parts per million
Total alkalinity	63 parts per million
Chlorides	25 parts per million
pH	8.1
Dissolved oxygen* two feet below surface of water	2.1 parts per million
Dissolved oxygen* in bowl at bottom of tank	1.8 parts per million

* Measured in tank with aluminum anodes.

Table V. Analysis of Deep Well Water

Total dissolved solids	414 parts per million
Total hardness	300 parts per million
Total alkalinity	276 parts per million
Chlorides	20 parts per million
Dissolved oxygen	0.4 parts per million
pH	7.3
Specific resistance at 20 C	1,240 ohms/cm³
Dissolved oxygen in water from bowl of tank	5.1 parts per million

Table VI. Reservoir Water Analysis

Total dissolved solids	42 parts per million
Total hardness	21 parts per million
Total alkalinity	18.6 parts per million
Chlorides	1.9 parts per million
pH	6.6
Specific resistance at 20 C	18,600 ohms/cm³
Dissolved oxygen	5.8 parts per million
Dissolved oxygen in water from bowl of tank	4.2 parts per million

It is interesting to note from Table III that the useful life of the aluminum alloy anode averaged 1,093 ampere-hours per pound of anode weight, whereas the useful life of the steel anode was less than one-third as great (334 ampere-hours per pound of anode weight). The marked superiority of aluminum anodes predicted from fundamental considerations thus actually is obtained in service.

Example *B*—100,000-Gallon General Service Tank

In 1939 the Dayton Power and Light Company found that a 100,000-gallon ellipsoidal-bottom elevated steel tank, erected in 1931, had developed numerous leaks in the bowl. The tank initially had been pointed with two coats of red lead paint. It was desirable to repair the tank with a minimum period during which it would be out of service. Therefore, the perforations in the tank walls were welded shut, and the deep pits were filled by welding. Then cathodic protection was applied. The anodes used initially were of number 303 stainless steel. Protection of the tank was satisfactory, but the anodes had a very short life because they developed severe localized attack. After several replacements, aluminum (2*S*) anodes were installed in 1943. These anodes were definitely more satisfactory because they developed a more uniform attack than did the stainless steel anodes used previously. When this tank was last inspected in 1945, it still was being adequately protected.

The water stored in the tank is from a deep well and has the composition indicated in Table V. The marked increase in dissolved oxygen concentration in water taken from the bowl of the tank can be attributed to the frequent fluctuations in water level which normally occur in tanks used for general service operation.

Example *C*—3,000,000-Gallon Municipal Standpipe

The Pennichuck Water Company of Nashua, N. H. in 1940 erected a standpipe 100 feet in diameter by 50 feet in height, having a capacity of nearly 3,000,000 gallons for water storage. The water confined is the typical New England surface water which has low mineral content but is extremely aggressive because of the high dissolved oxygen concentration and the absence of influencing amounts of cathodic inhibitors such as calcium bicarbonate. The composition is given in Table VI.

In order to overcome the effect of the high specific resistance of this water upon voltage requirements, 1,400 feet of 3/16-by-6-inch Alclad 24*S-T* sheet were used in the electrode configuration within the tank. Eleven volts were required to project a current flow of 30 amperes from the electrode configuration to the tank surface.

Pit depth measurements made with a dial depth gauge in the summer of 1945 indicate a maximum pitting rate of slightly over 0.001 inch per year on the submerged surfaces of the tank. Although

Figure 2. Photograph of portions of anodes of three aluminum alloys (2*S*, 17*S-T*, and 72*S* from left to right) used for 103 days in a 100,000-gallon steel water tank. The anode of 17*S-T* showed the most uniform attack and gave the highest over-all anode efficiency (89 per cent)

Table VII. Comparative Anode Behavior in Water Tank at West Carrollton, Ohio

Material	Service Hours	Ampere-Hours	Theoretical Weight Loss,* Pounds	Actual Weight Loss, Pounds	Over-all Anode Efficiency, Per Cent
2S	2,460	2,460	1.83	2.85	64
17S-T	2,460	2,460	1.83	2.05	89
72S	2,460	2,460	1.83	3.02	61

* Not corrected for presence of alloying constituents.

the applied current is not quite adequate to stifle the corrosion processes in this environment completely, it has reduced the rate of penetration of the steel standpipe to a negligible figure.

Examination of the aluminum alloy sheet electrodes at the end of 14 months operation indicated uniform attack with reasonable certainty of attaining approximately 100 per cent electrochemical electrode efficiency.

It is believed that the use of Alclad 24S-T as the anode material may have been a particularly good choice in this case. As is indicated in Table II, Alclad 24S-T is a duplex material consisting of a central core of an aluminum-copper alloy (24S-T) with a coating on both sides of aluminum. This coating probably resulted in even more uniform attack of the anode surface than would have been the case if plain 17S-T or plain 24S-T had been used as the anode.

Example *D*—100,000-Gallon Sprinkler Tank

A comparison of the electrode characteristics of anodes of three aluminum alloys, namely, 2S, 17S-T, and 72S, was made in a 100,000-gallon hemispherical-bottom elevated tank used for sprinkler storage by the Oxford-Miami Paper Company, West Carrollton, Ohio. Three electrodes—one of each of the types previously mentioned—three-fourths inch in diameter and $26^1/_2$ feet in length were positioned symmetrically within the tank so that identical potential conditions occurred on each electrode. The current flow from each electrode was controlled at one ampere. At the end of 103 days the electrodes were removed and examined. The copper bearing aluminum alloy (17S-T) electrode was found to be covered with an adherent crusty degradation product, including metallic copper particles deposited adjacent to the metal core. The 2S and 72S electrodes were covered with a less adherent and softer degradation product. Except for a few localized pits, the 17S-T had been consumed more uniformly than the 2S and 72S and did not have the intensified attack at the taped joints (Figure 2).

The behavior of the various anodes is compared in Table VII. It will be noted that the 17S-T electrode lost the least weight and had an anode efficiency of 89 per cent. The water confined in the tank is deep well water similar in composition to that stored in the tank of example *B*, in Dayton, Ohio. Evaporation and leakage losses are replaced by weekly filling to the overflow line.

Cathodic protection was applied to this tank in June 1945, at which time tubercles of red rust were observed oozing through breaks in the drying oil type paint film.

The extreme clarity of the water permitted visual examination of the hemispherical bottom of the tank some 30 feet below the water surface. This was also true after the cathodic protection system had been in operation three months, as all of the aluminum electrode degradation product appeared to have adhered to the metal anodes. This adhesion of corrosion products to the aluminum anodes is very desirable. With anodes of some other materials the products fall off and discolor or otherwise contaminate the water.

An examination of the tank at the end of three months of cathodic protection revealed the deposition of scale-forming salts over corrosion product noted earlier. Apparently cathodic processes, which generally produce a predominance of hydroxyl ions, were induced on the areas where the anodic processes resulting in metal wastage had occurred previously. The increase in pH of the rust tubercles caused the precipitation of the calcium and magnesium salts from the water in the form of a white precipitate consisting of $CaCO_3$ and $Mg(OH)_2$. It was interesting to note that none of the scale-forming salts were precipitated adjacent to the metal under the rust. Areas from which tubercles had been removed were found later coated with the white deposit and no further attack had occurred underneath.

Example *E*—Other Applications

In 1941 C. P. Hoover, Columbus, Ohio Water Department, began studies to establish methods for mitigating the corrosion in domestic hot water generating tanks.[3] Among the methods investigated was cathodic protection. A current of 0.35 amperes projected from an electrode centered along the vertical axis of the 30-gallon hot water generating tanks provided complete protection against Columbus, Ohio city water. Chrome steel anodes we found to be less satisfactory than aluminum (2S)—both from the standpoint of electrochemical efficiency, and the introduction of objectionable anode degradation products.

Many institutional and commercial hot water generating tanks now are receiving cathodic protection.

Cathodic protection can be applied effectively to intricate structures such as Dorr Clarifier mechanisms in municipal water treatment plants. An installation made on a 90-foot Dorr Clarifier at the Mahoning Valley Sanitary District, Youngstown, Ohio, reduced the average rate of pitting on the steel members of the rake arms from 0.0009 to 0.0001 inch per month.

Among the other structures submerged in water media to which cathodic protection is being applied are sewage digesters, deep well pumps, lock gates, Spaulding sludge blanket filtration softeners, and so forth. In addition to the applications mentioned previously, pipe line protection against soil corrosion is outstanding.

Cathodic protection provides a desirable electric load for the public utilities as the demand is relatively constant and continuous.

No Discussion

Electrification of the Cotton Industry in the South

S. A. BOBE
MEMBER AIEE

ALTHOUGH the South has advanced industrially in leaps and bounds in the past few years, especially during World War II, cotton still is "king" and remains the major industry. It employs the greatest number of people in manufacturing, 437,000, with a product value of $1^1/_4$ billion dollars. It further accounts for a farm income of $1^1/_2$ billion dollars. There is a total of 1,248 cotton mills of which 75 per cent are in the South.

Cotton accounts for 70 per cent of all textile fibers used, with rayon, wool, and jute accounting for approximately 12, 10, and 8 per cent.

To the electrical industry it represents a total of four million connected horsepower with an annual power consumption of nine billion kilowatt-hours. It uses all electric products from turbogenerators, motors, and lighting to recent installations of radio frequency heating for yarn twist setting.

These large quantities of power are comparatively recent. The industry, being one of the world's oldest, had carried development of mechanical drives to such a point of perfection that the economic necessity for change to electric drives was not as great as in other industries. As a result, the major share of electrification of the cotton industry has taken place in the past 20 or 25 years and still is not completed.

As large quantities of energy were required, early cotton mills, both in New England and the South, were located along streams or rivers. Dams were built and mechanical water wheels installed driving by belts or ropes to mill line shafts. A common arrangement was to have one large grooved rope pulley, driven by the water wheel, located in a ropeway at the end or center of the mill. Ropes then were run in this ropeway from the large pulley to a line-shaft pulley at each floor level. All of the mill equipment then was driven by belts from these line shafts.

With the development of large reciprocating steam engines, mills ceased being dependent on water power and began to move to locations having advantages of raw material and labor supply. This marked the beginning of large scale movement of the industry from New England to the South. The steam engines still used the same power distribution arrangement as the water wheel with usually one large engine driving a complete mill. Such a drive is illustrated in Figure 1.

These large slow-speed steam engines were a very impressive sight with the engine room kept painted and clean and all brass oil cups and governor parts highly polished. Such engine drives now are practically extinct.

The first introduction of electric energy in the cotton mill came as a means to secure safer and better lighting. Small generators were installed driven from the mill line shaft or from small steam engines. The output of these generators was distributed through open knife switch panel boards to drop cords throughout the mill. Some of these original installations, including the drop cords, still occasionally can be found in small mills.

With generators and motors both available, cotton mill operators now found it possible to arrange mills for best equipment location without being limited by a

Figure 1. Reciprocating steam engine driving cotton mill by means of ropes to line shafts at different floor levels

S. A. Bobe is an industrial engineering supervisor with Westinghouse Electric Corporation, Atlanta, Ga.

Figure 2. Flow sheet of cotton through a textile mill

Figure 3 (above). Output end of variable voltage sectional motor drive of cloth finishing machine showing last motor and motor-generator set with control

common mechanical drive. This resulted in the water wheels or steam engines being used to drive large generators which supplied electric energy to motors driving short sections of line shafts.

In most cases the early electrified mills were those that generated their own power. It was not until large power systems were organized that mills were able to purchase the large quantities of dependable power required at economical rates. These rates have been decreasing continually and dependability increasing until now most mills can purchase power cheaper than they can generate it. Average mill power costs in the South vary from about one cent per kilowatt-hour for the smaller mills to five mills per kilowatt-hour for the larger users.

The next step from a common line-shaft drive was to provide individual motors on each separate piece of equipment or process. This was a quite logical result as demands were made for higher speeds and cleaner mills. Individual drives gave closer output control by eliminating unpredictable belt slip and permitted unlimited flexibility in arrangement. Machines were arranged for best mill arrangement without concern about drives. As a result all new mills, and almost all old mills, now are nearly completely individually driven. The trend to increase machine speed and output is still continuing, however, and resulting in an increasing kilowatt-hour consumption and investment in machinery per employee.

In the early electrification of cotton mills the question of voltage was given serious consideration and 550 volts adopted as standard for mill distribution. The major reason was saving in copper without increasing costs of motors or con-

trol over 440-volt cost. The rating of 550 volts is now standard in approximately 95 per cent of the mills in the Southeast including both cotton and rayon. Although recent efforts have been made to change this to 440 volts, the textile industry still considers 550 as standard and all new construction continues at 550 volts.

The kilowatt demand of cotton mills will vary from 1,000 for small units to approximately 15,000 for the largest groups. When power is purchased it is brought to the mill at high voltage and then transformed to the mill distribution voltage. The substations usually are owned by a power company. Past practice was to supply a single bank for the complete mill load. This resulted in many transformer banks of 5,000 and 7,500 kva, or even larger, with resultant high currents and high short-circuit capacities. Short-circuit interrupting capacity was not given sufficient consideration always and many present installations do not have adequate protection in this respect. The modern trend is to split up transformer banks into small units of 750- or 1,000-kva capacity and feed portions of the load independently with breakers available for emergency tie-in.

Busses from the transformer secondary winding usually carry the power to a switch room and main distribution board located in the mill. The board includes feeders to the various sections of the mill with indicating and totalizing meters. Past practice was to use manual oil circuit breakers with current limit protection. Modern boards use drawout type air breakers in cubicle construction with both instantaneous short circuit and thermal or inverse time limit feeder protection.

Where modern use of small power transformers is made, present practice tends towards unit substation construction. This includes the transformer, distribution feeder breakers, meters, instruments, and relays all assembled as a factory made unit. This has been carried a step further in some mills now under construction with the unit substation transformer being air cooled or noninflammable liquid cooled, and the complete assembly located inside of the mill.

Power distribution from the switchboard to individual motors is made in the usual manner by conduit feeders, with air breaker or fuse feeder protection. Bus duct has been installed recently in a number of mills in place of conventional conduit and cable. Line starting now is used exclusively for even the largest motors except on some applications such as roving frames where a soft start is required. In these special applications automatic step resistance-type starters now are used.

The average mill will have a connected horsepower of approximately two times the maximum kilowatt demand with the continuous load being nearly equal to the maximum demand. During World War II, and at present, most mills operate 24 hours per day with two full shifts and one part shift. This third shift is used to balance out bottlenecks as very few mills have such a perfect balance of output in all divisions that no shortages result.

Mills having complete individually driven equipment usually have an overall power factor of 75 to 80 per cent. Those with a large share of line shaft drives using higher horsepower motors will average 82 to 86 per cent Some power companies in the Southeast have very attractive power factor rates making the installation of capacitors to correct power factor a high return investment. Most such applications pay for the capacitors in one to two years time. Other utilities provide an optional penalty which they may enforce if the maximum demand power factor drops below 85 per cent. The majority of capacitor installations are of the distributed type with small groups of capacitors being connected to feeders or at larger individual motors.

Cotton Processing

After cotton is picked it is collected loose, in wagons, and taken to the local cotton gin. Here the seed is separated from the fibers by the ginning machine. This machine consists essentially of a series of saws so spaced that the seeds just will pass between the saws. As cotton is fed to the gin the seed is cut out, after which the fibers are carried by suction to the baler. The average bale of cotton weighs 500 pounds but requires 1,500 pounds of cotton bolls before ginning. The other 1,000 pounds are mostly seed with attached short fibers and some small

Figure 4 (above). Picking room showing cotton lap rolls forming at output end

Figure 7 (right). Spinning frame driven by textile motor with special above-floor mounting and variable pitch V-belt drive

amount of trash. A complete cotton gin, including blowers and conveyors, usually is operated by a 75-horsepower wound rotor motor.

This 500-pound bale of cotton is the standard unit used in records on size of crops, surplus, and manufacturing. It may be stored almost indefinitely without spoiling. The average crop in this country is 10 or 12 million bales of which 8 to 9 million bales are processed.

In converting this 500-pound bale of cotton fiber to cloth there are 45 pounds of waste. It requires approximately 850 kilowatt-hours of electric energy and 100 man hours of labor.

Figure 2 shows a typical flow sheet of a complete cotton mill. All mills do not have all of the operations shown. The more common divisions are yarn mills, cloth mills, and finishing plants. The first group prepares yarn only, starting with baled cotton. This yarn is usually for specialized use such as electrical insulation, sewing thread, tire cord, and knitting. This group uses 18 per cent of the total cotton processed. The second group, which includes the greatest percentage, starts with the raw cotton, follows through all the processes including weaving, but does not dye or print the cloth.

Finishing plants take the woven cloth and wash, bleach, dye, print, fill, and calender as necessary for the various types of cloth called for by the modern market. They usually are separate plants and finish cloth for groups of mills. Their processes involve the use of chemicals, dyes, and large quantities of process steam. Power sometimes is generated as a by-product of this steam but the trend is away from this combination with the decreasing cost of utility power. Electric drives in finishing plants are principally direct current because of the necessity of variable speeds for different weight goods and different finishes. D-c adjustable voltage range drives including several sectional motors operating in tandem are common as most of the washing, bleaching, and dyeing processes are now continuous. Such a range drive is shown in Figure 3.

Mill Drives

As previously mentioned, most all equipment in cotton mills now is driven by individual motors. The major exception has been carding but even this is now beginning to be changed. Electric equipment with standard enclosures is usually satisfactory except in the case of motors. Because of the great amount of free lint, standard open motors will plug up quickly and lose their ability to cool. As a result, most manufacturers make a special textile motor with large ventilating openings and smooth surfaces so that lint easily will pass through the motor without being caught. In the smaller sizes of two horsepower and below, totally enclosed nonventilated assemblies are used. A recent development has been the use of prelubricated sealed ball bearings in textile motors. These bearings do not require any attention, including lubrication, for periods of five years or longer and result in a cleaner mill.

A breakdown of power consumption in an average mill shows the largest share, or about 50 per cent of the total, is used in spinning. The next largest is 20 per cent for weaving. The remaining 30 per cent is divided between opening, picking, carding, drawing, roving, warping, slashing, and miscellaneous uses such as lighting, ventilation, pumps, and elevators.

To show more clearly how horsepower is distributed in what might be called an average mill, Table I lists the actual installed horsepower in one such mill.

Opening and Picking

This operation involves taking the baled cotton, breaking it loose, fluffing, beating, cleaning, and forming a thin layer about 40 inches wide which is called a lap and collected in a roll. This involves the use of 3-, 5-, and $7^1/_2$-horsepower

Table I. Distribution of Horsepower in a Typical Cotton Mill

Demand, 948 Kw

	Connected Horsepower	Percentage of Connected Horsepower
Opening and picking	215	8.0
Cards	505	18.7
Drawing	15	0.6
Roving	40	1.5
Spinning	1,117	41.5
Warping	20	0.8
Slashers	30	1.1
Weaving (looms)	400	14.9
Miscellaneous	345	12.9
Total	2,687	100.0

Figure 8. Installation of twisting frames driven by textile motor

motors of 1,160- and 1,750-rpm speeds. The motors are line started and usually interlocked in sequence as the process includes air and belt conveyors which must be protected against overflow. A typical picking room is shown in Figure 4.

Cards

Cotton cards still usually are driven from a line-shaft drive with 30 to 50 cards tied to a single line shaft driven by a single motor. Average 40 or 45 inch cards require $1^1/_4$ horsepower for normal running. Two problems complicate the use of individual card motors.

1. The requirement of a high breakaway and accelerating torque necessary because of the large diameter and weight of the cylinder.

2. The close overload protection which must be provided because of frequent card packing and quick overload build-up.

When using a $1^1/_2$-horsepower motor, which is ample for normal running, the starting torque must be at least 300 per cent of full load to provide for breakaway and acceleration. Overload relays used must permit the long accelerating period of approximately 30 to 45 seconds and still be sensitive to both quick or slow overload build-up. A standard thermal overload device must be supplemented by shunts or a thermostat on the motor itself.

The average cotton card cylinder with its driven pulley operates at a speed of 165 rpm, and is driven by a 870- or 1,160-rpm motor. The required power will vary as the square of the cylinder operating speed. Cotton mills will have from 50 to 500 cards, depending on the size of the mill and the quality of yarn being made.

Figure 9 (below). Curves used in estimating horsepower requirements of spinning frames

A—2-inch diameter ring
B—$2^1/_2$-inch diameter ring
C—3-inch diameter ring

The output of the card is in the form of a fleecy strand of cotton about one inch in diameter and called a sliver.

Control equipment is commonly a magnetic or manual line starter with some reversing device as the card must be reversed for stripping or cleaning. A typical individually driven card is shown in Figure 5.

Drawing

After carding, the cotton fibers may be combed to eliminate short fibers, as in the case of fine combed yarns, or go direct to drawing frames. At the drawing frames the fibers are aligned further and straightened by means of a series of rolls each of which runs faster than the preceding one. With the rolls being spaced greater than the longest fiber length this results in a further drawing and straightening of individual fibers.

This operation uses only a small amount of power. Floor mounted gear motors or low speed textile motors drive the frame shafts which operate at 250 rpm. The average requirement is six sliver deliveries per horsepower. Motors are usually line-started. Figure 6 shows a typical installation using a gear motor.

Roving

The next operation involves roving which combines the required number of fibers for the weight yarn to be made, further draws the yarn, and slightly twists while winding on large bobbins in preparation for spinning. Average roving frames require 3- and 5-horsepower textile motors with speeds of either 870 or 1,160 rpm. It is necessary that roving frames start slowly since the yarn is yet very soft with no twist and low strength and may be broken easily. This soft starting

Figure 10. Drum driven warper

Figure 11. Output end of variable voltage sectional driven slasher with core driven beam

is accomplished either by using a closely applied motor with low starting torque and line-starting or a larger motor with primary resistance type starter.

Spinning

This is the operation wherein the greatest percentage of power in a cotton mill is consumed. The yarn is pulled by a set of rolls which further draw the fibers and feed to a spindle rotating at high speeds, in the order of 7,000 to 10,000 rpm, depending on yarn weight. A small traveler which rotates in a ring guide around the spindle acts as a guide for the yarn.

Average spinning frames consist of 200 to 250 spindles. There may be differences in the size of bobbins, spindle speeds, and amount of twist obtained. Required horsepowers for individual motor drives range from $7^1/_2$ to 20 horsepower at 1,750 rpm with some at 1,160 rpm. Textile-type motors must be used since the lint content in the air is quite high. Line-starting is standard with combination starters usually mounted on the end of the frame. The horsepower required varies about as the 1.5 power of spindle speed. Other factors effecting the horsepower are ring diameter, amount of drawing effect of feed rolls, and size of yarn handled.

There are two general types of spinning called filling and warp. Filling spinning is for yarn used in the woof or cross threads in cloth. It is usually lighter and is usually spun onto bobbins used in loom shuttles. Warp yarns are usually heavier with more twist and wound on larger bobbins.

Another variation of spinning is twisting which combines and twists spun yarns together to get greater weight or strength. These machines are essentially duplicates of spinning frames except that no drawing is included in the feed rolls.

After yarns are twisted they are completed except for any treatment that may be required to prepare them for weaving. In the case of the filling or woof none is usually necessary. Warp yarns, however, must be wound on beam rolls of approximately the width of the cloth to be woven. Further, the individual yarns are sized or starched to give them greater strength and abrasion resistance. This is necessary in weaving for the yarn to withstand the shuttle friction.

Figure 7 shows a cotton spinning frame and Figure 8 an installation of twisters. Figure 9 shows a typical set of curves used in applying motors to spinning. These are simplified curves for normal applications.

Warpers

The winding of the yarn from bobbins or spools onto beams is done on a warper. This may be either a drum or core type warper with the first using a constant speed induction motor and the second either multispeed squirrel cage or variable-speed direct current. The average mill will have two to ten warpers. Motors are three or five horsepower line-started and equipped with brakes for quick stopping. Drop wires automatically stop the warper whenever a feed thread is broken. Figure 10 shows a typical warper installation.

Slashing

The operation of yarn starching is known in textile terms as slashing and the machine as a slasher. Any faulty slashing is quite costly in that it results in excessive loom stoppages with loss of production and lower grading of cloth because of more warp knots. To provide more exacting tension and speed control a modern slasher drive uses adjustable voltage direct current with sectional motors and a tension regulated beam windup.

The slasher consists of a stand on which unstarched beams are mounted, a size box with rolls for depositing wet starch on the warp, a set of steam drying cylinders or a hot air drying chamber, a delivery roll for pulling the yarn and a beam roll for winding up the finished warp. Individual motors are applied to the size box, delivery roll, and the beam in order to provide tension control between these sections. Occasionally motors also are applied to cylinders. Because of low driven speeds required, gear motors usually are used with floor mounting and driving by chain to their respective rolls The starch and delivery rolls are usually 9 inches in diameter and the beam roll starts on a 6-inch core and builds up to between 24 and 30 inches when full. Usual speeds are four to five yards per minute for creeping and threading with operating speeds of 20 to 65 yards. Some newer slashers are operated as high as 100 yards per minute. A typical slasher would have a $1^1/_2$-horsepower motor on the size box or boxes, a 3-horsepower motor on the delivery roll, and a 5-horsepower motor on the beam windup.

Figure 12. Elementary diagram of sectional driven slasher showing arrangement of rotating regulator field circuits. Series and regulating fields are accumulative and tension field differential

Figure 13. Oscillograph of test on $1^1/_2$-horsepower 6-pole motor driving a loom at 160 picks per minute with low slip rotor and showing regeneration each pick

The beam windup motor must operate over the entire speed range of the slasher with either an empty or full beam and maintain constant a preset yarn tension. It replaces a slip clutch on the old mechanical drives which permitted greater slippage as the beam filled up. This resulted in uneven winding tension with soft and hard spots in the finished beam and tangles and breaks at the loom.

A five-to-one speed range motor by field control is used with the shunt field, energized by a Rototrol (rotating regulator). The Rototrol has three fields.

1. A differential pattern field excited from the constant potential exciter and in series with a tension adjusting rheostat.
2. An accumulative field sensitive to beam motor armature current.
3. The usual series field to obtain amplification.

The Rototrol maintains constant armature current with changing speed by changing the motor field current. This results in varying motor output torque as necessary to maintain constant yarn tension with changing diameter.

The control includes necessary starting equipment for the motor generator set, a motor operated rheostat to give smooth acceleration and deceleration, tension control stations for each motor, a preset speed control rheostat, and several "start-stop-slow" pushbuttons. Figure 11 shows the output end of a slasher showing the beam and control station. Figure 12 is an elementary diagram of the electric equipment.

Weaving

All yarn processing as described is necessary to prepare cotton so that it finally may be woven into cloth. The operation of weaving is still the same as in ancient days in that a shuttle must be thrown between warp threads alternately from one side to the other. Now, however, it is done at high speeds by machines rather than slowly by hand.

An average cotton mill will have from 400 to as high as 3,000 looms. Many still are driven by line shafts and flat belts but the number is being reduced steadily.

The present standard motor drive is an enclosed nonventilated motor mounted on the loom and driving by pinion a loom main gear. These main gears average about 175 teeth. The motor pinion will vary as determined by loom and motor speeds. For ordinary cloth of weights similar to sheeting, looms will operate at 175 to 210 picks, or shuttle throws, per minute. For heavier goods or intricate weaves the speed will be reduced to possibly as low as 100 picks for heavy duck.

When first individually motorized, the majority of looms required 1/2- and 3/4-horsepower motors. Since that time loom speeds have increased steadily until at present the 1-horsepower rating is most common with some $1^1/_2$ and 2 horsepower, but no new installations are below 1 horsepower.

The atmosphere in a weave room is very linty and it is necessary to protect the motors. As loom motors are small, totally enclosed motors rather than lint-free were adopted as standard. These motors, however, are rated at a 40 degrees centigrade continuous rise rather than the usual 55 degrees centigrade. There are two reasons for this rating

1. The motor must be able to pull the loom during the breaking-in period when the great number of new tight bearings cause extra loading.
2. A loom load is of pulsating nature and the motor losses and heating are higher than for an equivalent steady load.

Early loom motors used standard motor parts which were usually of low inertia and resulted in the motor passing from motoring to regeneration with each loom pick. This is illustrated clearly in Figure 13 which is an oscillograph of such a motor in operation. As a result of considerable study and test, present motors have a more nearly correct balance of motor inertia to match the loom, eliminating the regeneration and increasing motor effi-

Figure 14. A modern weave room installation with individual motor on each loom

ciency on this type of load. Efficiency is an important factor where hundreds of motors are operated in a single room.

Individual loom motors are controlled by manual switches at the motor which include some thermal device for overload protection. Several motors are grouped on a common feeder protected by an air circuit breaker located in a distribution panel. The number of motors tied to one feeder is determined by the size of circuit breaker permitted by the wire used and thermal capacity of the individual motor starter thermal overload elements. This feeder breaker must hold in when the looms all are line-started simultaneously. With 1-horsepower 550-volt motors, eight usually are grouped together on one 25-ampere breaker. It usually works out for a convenient physical arrangement that about 50 looms can be handled from one panel board. The feed to this panel board is supplied through a magnetic contactor so as to give undervoltage protection and permit starting of the group from one push-button station. A modern weave room is shown in Figure 14.

Conclusion

This has been a brief outline of cotton manufacturing with the object of showing the importance of the industry as an electric power consumer and user of electric equipment. All types of electric equipment are used from central station generating equipment through motors and control to modern electronic devices.

The industry is vitally interested in new developments such as new motor insulation, unit substations, dielectric heating, electrostatic air cleaning, air conditioning, and electronic drives.

Discussion

A. T. Bacheler (Westinghouse Electric Corporation, East Pittsburgh, Pa.): I first want to congratulate Bobe on his fine paper on the electrification of the cotton industry in the South.

There are a few items which might be discussed in greater detail than was possible in his paper. Bobe mentioned the regulation of warp tensions at the slasher beam, using the armature current of the beam motor as the cue to the tension obtained. In some instances this is not a sufficiently accurate indication of the tension from empty to full beam to produce the desired results especially when regulating for light tension on drives designed to permit greater tensions to be obtained. One of the factors producing error is the no load current of the motor, and this is especially true at light tension where the tension load may not be much greater than the losses. At full field the no load current of the motor is much less than at weak field since the windage of the motor, friction, and core losses are greater at the higher speed. Also, when gearing is used, the gearing losses, including churning of oil and friction at the oil seals, must be considered. These losses also increase at the higher speeds of the beam motor. Therefore, if the regulator maintains constant armature current, the tension at empty beam will be less than at full beam. A satisfactory solution to this problem has been devised and consists of a circuit which reduces automatically the value of regulated armature current as the beam builds up. Thus, the tension is held much closer to the desired optimum value from empty to full beam without the use of dancer rolls or other devices operating on the diameter of the beam.

It might also be desirable to mention electronic applications which are being made in the textile industry in the South. I shall mention two typical applications.

An all-electronic warper drive has been built and installed in one of the southern mills. The armature power and field excitation of the direct current drive motor are both provided by grid controlled mercury arc rectifiers operating from the alternating current power supply. This drive is essentially a standard electronic drive combined with an electronic speed regulator to hold warp speed constant. A pilot generator is used to indicate warp speed, and the speed range for warp speed and build-up on the beam is obtained by a combination of armature voltage and field control. Several more of these electronic units are being built.

An electronic relay has been developed for use on loom, warper, and knitting machine stop motions involving drop wires or other contact making devices which operate when a thread is broken. Sometimes these devices do not make contacts of low enough resistance to operate magnetic relays. The electronic relay has been designed to overcome these difficulties and provides reliable operation on contacts of high resistance due to dirt and lint. This relay uses a thyratron tube whose firing is initiated by the drop wires connected in the high impedance grid circuit. In the plate circuit of the thyratron is a small magnetic relay which handles the control circuit which stops the drive.

A modification of the electronic relay has been applied to loom bobbin feeler mechanisms, where the time of electric contact between feeler and bobbin is too short and the resistance may be too high for dependable operation of a magnetic relay. As soon as the yarn on the bobbin runs out, firing of the thyratron is initiated by the feeler which makes contact with the bobbin. A high resistance of the order of half a megohm is placed in the thyratron grid circuit so that the actual contact resistance becomes negligible. The thyratron operates on direct current and, once fired, keeps on conducting until a magnetic relay in the plate circuit has picked up. The magnetic relay initiates a change of bobbin and deenergizes the thyratron so it will be ready for the next operation.

The Physics of Electronic Semiconductors

G. L. PEARSON
NONMEMBER AIEE

SEMICONDUCTORS have a number of unique properties which make them useful in the design of electric circuit elements. Their electrical resistivities near room temperature fall in the range 10^{-2} to 10^{-4} ohm-centimeters. In comparison, the resistivities of typical metals in this temperature range are around 10^{-6} ohm-centimeters and those of insulators between 10^{6} and 10^{15} ohm-centimeters or higher. The electrical resistivities of semiconductors and insulators decrease rapidly with rise in temperature, while those of metals increase relatively slowly. The resistivities of dry rectifiers, which consist of a metal in contact with a semiconductor, may change by a factor of 1,000 as the sign of the applied potential is reversed. The purpose of this paper is to outline the present theories relating to semiconductors and to correlate these with quantitative experimental data obtained on some typical semiconducting samples.

Semiconductors may be classified on the basis of their current carriers into electronic, ionic, and mixed conductors. In ionic and mixed conductors, ions are transported through the solid, thus changing the composition of the material. As this leads to unstable characteristics, only those substances in which the current is carried solely by electrons will be discussed here.

As early as 1900 Drude[1] suggested that the high electrical conductivity of metals (low resistivity) was due to the large number of so-called free electrons. These electrons are free in the sense that under the action of an electric field they move through the crystal lattice, thus carrying a current. Their number is of the order of one per atom or approximately 10^{23} per cubic centimeter in most metals, and this density does not change appreciably with change in temperature. In the modern theory of semiconductors and insulators as proposed by Wilson[2-4] around 1930, it is shown that most of the electrons in these substances are bound to their respective atoms, thus leaving only a small fraction of the electrons (1 per 10^{8} to 10^{9} atoms) free to conduct current. Furthermore, the number of such electrons increases rapidly with increase in temperature, thus accounting for the high negative temperature coefficient of resistance in semiconductors and insulators.

The physical picture of a metal consists of an electron gas formed by the free electrons in which the positive ions float. As the ions repel each other, they tend to arrange themselves so as to use their space to the best advantage, which requires that they take up some close-packed crystal arrangement such as body-centered cubic, face-centered cubic, or close-packed hexagonal. By means of X-ray analysis Grimm[5] has determined, as shown in Figure 1*B*, the electron charge density in the metal magnesium for the base plane of the close-packed hexagonal lattice. This figure is drawn to scale, the unit being angstroms (1 angstrom $= 10^{-8}$ centimeter). It is seen that the valence electrons give a uniform negative charge in which the positive magnesium ions are imbedded. The heavy density near the lattice points is from the electrons bound to the ions. Figure 1*A* gives the electron density in the insulator diamond as determined by Grimm for the 110 plane of the face-centered cubic lattice. Although the positive carbon ions are imbedded in the negative charge of the valence electrons, it is seen that spherical symmetry is lacking and the electrons are concentrated along the shortest paths between atoms.

Band Theory of Solids

If all of the charge in the electron gas were free to move through the lattice under the influence of an electric field, Figures 1*A* and 1*B* indicate that diamond and magnesium should be equally good conductors. Measurements show, however, that at room temperature magnesium is more conducting by a factor of 10^{18} and therefore we must add something to our picture to explain this enormous difference. This was one of the major problems of the physics of solids which had to wait until the advent of quantum mechanics around 1930 for a solution. Although the problem is now completely solved, the solution is so wrapped up in mathematical language that it can not be presented here. It can be said that solids, like free atoms, are pictured as having a large number of discrete energy states with one and only one electron allowed in each individual state. These energy states arrange themselves into bands, the structure of which determines the properties of the solid. Just as automobiles in a parking lot are unable to move when they are parked bumper to bumper, so the electrons in a solid are immobile when every energy state in the band is filled with an electron. When there are unoccupied states in the band, the electrons move under the action of an electric field and the material is a conductor. A semiconductor has only a few electrons in a conduction band (a band with energy states only partially filled) at room temperature, but this number increases with increase in temperature. These ideas are represented graphically in Figure 2 where the black areas represent

Paper 47-34, recommended by the AIEE committee on basic sciences for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted October 31, 1946; made available for printing December 5, 1946.

G. L. PEARSON is with Bell Telephone Laboratories, Inc., Murray Hill, N. J.

Acknowledgment is made to J. H. Scaff and H. C. Theuerer for furnishing the silicon samples described in this paper and to E. F. Kingsbury for contributing Figure 5*A*. A great deal of helpful criticism was received from J. Bardeen during the preparation of this paper.

allowed energy levels filled with electrons, the white areas represent forbidden regions where no energy states exist, and the shaded areas represent conduction bands. Energy is plotted vertically on an arbitrary scale. The width of the forbidden region may vary from zero to ten electron volts (one electron volt is the energy required to move one electron through a potential difference of one volt). Figure 2*A* indicates the conditions existing in an insulator where all the electrons are in filled bands and the forbidden region is so wide, several electron volts, that thermal agitation is incapable of exciting electrons from the filled band into the conduction band. In a semiconductor (Figure 2*B*) the energy gap between the filled and conduction bands is small, one electron volt or less, so that electrons from the completely filled band may be thermally excited to the conduction band, thus producing a conductivity which increases with temperature. In some metals such as magnesium, the energy gap between the filled and unfilled bands is zero as shown in Figure 2*C*, and in others such as the alkali metals the lower band is only half filled with electrons (Figure 2*D*). In either case conduction is good at any temperature.

Semiconductor Classifications

More detailed representation of the electron arrangements in the energy bands of chemically pure semiconductors and of those containing small amounts of different types of impurities are shown in Figure 3. Figure 3*A* is for pure semiconductors which have been termed intrinsic. At any temperature T an average number n of electrons are excited thermally from the lower filled band to the upper band. Conduction then can take place both by means of the electrons in the upper band and holes in the lower band, which is now not quite full. In the latter mechanism the sign of the carrier charge appears to be positive.

In most semiconductors the conductivity is highly dependent on the impurities present in the sample. By impurities we mean added foreign atoms, physical defects in the lattice, or differences from stoichiometric composition. It is assumed that the impurities introduce extra energy states in the normally forbidden region between the bands as shown in Figures 3*B* and 3*C*. Electrons in these impurity states are localized in the neighborhood of the impurity and cannot take part in conduction. Two types of impurity are possible. In the donator or N-type shown in Figure 3*B* the impurities carry extra electrons with them and usually have energies near the conduction band. Since the energy gap E_1 is much less than E, electrons are thermally excited at lower temperatures than in an intrinsic semiconductor. At very low temperatures the extra electrons are all bound to the impurity atoms; at higher temperatures these electrons are thermally excited to the upper band where they may conduct. At still higher temperatures the donator electrons may all become excited so that the number of conduction electrons remains constant with further increase in temperature until the thermal energy becomes great enough to excite intrinsic electrons from the lower band. An impurity semiconductor turns into an intrinsic semiconductor at high temperatures. At low temperatures the number of excited impurity states and, therefore, the conductivity at a given temperature increase with the amount of impurity present.

Figure 2. Energy level diagrams for solids

The clear regions are forbidden, the dark areas are allowed and full, the shaded areas area allowed but empty

A. An insulator
B. A semiconductor
C. A metal with overlapping filled and conduction band
D. A metal with half filled band

In the acceptor or P-type impurity semiconductor shown in Figure 3*C*, the extra states lie near the filled band. At very low temperatures these states are all empty, but on heating, electrons from the lower band are excited into them. Although the excited electrons are bound, hole conduction is possible in the lower band.

In an intrinsic semiconductor the conduction is by an equal number of electrons and holes, in an N-type conduction is solely by electrons at low temperatures and by electrons and holes at high temperature, and in a P-type solely by holes at low temperatures and by electrons and holes at high temperatures. In addition to explaining the magnitude of the conductivity and temperature coefficient, we will see that this picture clarifies certain anomalies in the Hall and thermoelectric effects in semiconductors.

Electrical Resistivity

ρ in ohm-centimeters is

$$\rho = Ae^{E/2kT} \qquad (1)$$

where A is a factor which varies relatively slowly with temperature, T is the temperature in degrees Kelvin, k is Boltzman's constant (8.69×10^{-5} electron volts per degree), and E is the energy gap between the two bands in electron volts. From equation 1 it can be seen that a plot of log ρ versus $1/T$ for an intrinsic semiconductor should give a straight line the slope of which is equal to $E/2k$ or 5,750 times E in electron volts. Figure 4 is such a plot for silicon containing different amounts of impurity. Curve A was obtained from measurements made on a block of silicon prepared from a melt of high purity material obtained from du Pont. Curve D is from a block of the same material to which 0.03 atomic per cent of boron had been added. Curves B and C were obtained from silicon samples containing intermediate amounts of unknown impurities. At the higher temperatures the resistivities of all the samples fall on the same straight line in accordance with our picture of semiconductors in the intrinsic range. The slope of this line indicates that the energy gap between the filled and unfilled bands in silicon is 1.2 electron volts. At lower temperatures the resistivities do not continue to follow the intrinsic line, but branch off at increasingly higher temperatures with increase in impurity. In the branch curves, the number of intrinsic electrons and holes becomes small compared with the number excited from impurity states and the resistivity is determined by the amount of impurity present. The decrease in resistivity just beyond the branch point is not associated with a change in the number of excited impurity states, but rather arises from a decrease in mobility resulting from the heat motion of the ions in the lattice.

Figure 6. Schematic circuit arrangement for the measurement of Hall coefficient in semiconductors

Sign conventions are as shown

This is a complicated story and will not be discussed here. On going to still lower temperatures the impurity resistivity increases and an estimate of the energy gaps E_1 or E_3 can be made from the slopes.

Although sample A is the purest silicon we know how to prepare, even this material must contain some impurity, as defined above. At room temperature the addition of three boron atoms for each 10,000 atoms of silicon in sample D reduced the resistivity by a factor of 500 as compared with sample A. This indicates that A is pure to about one atom in five million so far as conductivity is concerned. If absolutely pure silicon, which followed the intrinsic line to room temperature, could be obtained its resistance would be

Figure 7. Schematic circuit arrangement for the measurement of thermoelectric power in semiconductors

Sign conventions are as shown

Figure 8. Logarithmic plot of the current versus voltage characteristic for a P-type silicon point contact rectifier

Figure 9 (right) Logarithm of the resistivity of two thermistor materials as a function of inverse absolute temperature

greater than that of sample D by a factor of 10^7 at room temperature. This would require impurity of less than one atom for each 10^{11} silicon atoms.

Resistivity measurements such as those shown in Figure 4 have been made on other materials which have intrinsic characteristics. The values of the energy gap E in electron volts are shown in Table I. Diamond, of course, is an insulator at ordinary temperatures but it, like most other insulators, has a high negative temperature coefficient of resistance and shows intrinsic characteristics at very high temperatures.

The values of the energy gaps E_1 and E_2 due to impurities can be deduced in like manner from measurements made at low temperatures. As these vary both with the variety and amount of impurity, no quantitative values will be given, although in general they lie between 0.001 and 0.3 electron volt.

Photo Effect

In addition to an increase in conductivity with rise in temperature, many semiconductors show increased conductivity on exposure to light of the proper wave length. This arises from the fact that just as electrons can acquire enough energy thermally to excite them from the filled band to the conduction band, so they may acquire sufficient energy optically to produce the same result. The fundamental equation giving the energy of a quantum of light is

$$E = \frac{hc}{\lambda} \qquad (2)$$

where E is the energy in electron volts, h is Planck's constant (4.1×10^{-15} electron volt per second), c is the velocity of light (3×10^{10} centimeters per second), and λ is the wave length of the optical radiation in centimeters. The energy of a light quantum in electron volts according to equation 2 is 1.236 divided by the wave length of the radiation expressed in microns (1 micron $= 10^{-4}$ centimeter). The wave length of the sodium D line in the yellow part of the visible is 0.589 micron and the quantum energy is 2.1 electron volts, which is sufficient to excite electrons from the filled to the conduction band in germanium, silicon, cuprous oxide, and boron, but is insufficient to excite electrons in diamond. Radiation of 1.5 microns, situated in the infrared, has a quantum energy of 0.82 volt and cannot excite any of the semiconductors shown in Table I excepting germanium. By equation 2 only wave lengths shorter than 1.05 microns have energy equal to or greater than the 1.2 electron volt energy gap in intrinsic silicon. Light longer than this wave length should pass through silicon without absorption but shorter wave lengths should be absorbed and cause photoconductivity. Figure 5A is a plot of the ratio of the light transmitted to the light incident on a thin film of silicon as a function of the wave length λ expressed in microns. At wave lengths longer than 1.2 microns the transmission is about 67 per cent, the remainder being reflected. At some wave length between 1.0 and 1.2 microns, absorption sets in and the transmission falls off with decrease in wave length. Figure 5B, which was obtained by Teal[9] and his collaborators, gives the ratio of the change in resistance to the dark resistance when light of constant energy per square centimeter but varying wave length falls on a film of high purity silicon. It is seen that the resistivity is little affected by long wave-length radiation, but photoconductivity sets in around 1.2 microns and increases sharply below 1.0 microns. The decrease in photoconduction below 0.8 microns is not completely understood, but it is thought the large absorption in this wave-length region keeps the excited electrons near the surface where they recombine with the ions before producing photoconduction.

Table I

Material	E in Electron Volts
Diamond[3]	7
Boron[3]	2
Cuprous oxide[7] (Cu_2O)	1.4
Silicon	1.2
Germanium[8]	0.76

The Hall Effect

Fundamental information about the mechanism of conduction in semiconductors can be obtained from studies of the Hall effect. In 1879 Hall[8] discovered that a potential difference may be produced across a strip of metal which is carrying a current by placing the strip in a magnetic field. Consider a rectangular plate in the plane $Z=$ zero, with edges parallel to the X and Y axes as shown in Figure 6. If a current I from an external battery flows in the X direction and the sample is placed in a magnetic field H in the Z direction, a transverse electric potential V is produced between the terminals A and B. The magnitude of this potential in volts is given by the equation

$$V=\frac{10^{-8}RIH}{t} \tag{3}$$

where I is the current in amperes, H the magnetic field in gausses, t the thickness of the sample in centimeters, and R the Hall coefficient in centimeters cubed per coulomb.

The Hall effect occurs because the magnetic field causes the electrons in the sample to travel in curved paths, thus charging up the sides of the conductor until a transverse electric field exists of just the right magnitude to cancel the effect of the magnetic field and make the electrons travel through the solid undeviated. Under the conditions shown in the figure, the terminal A should be negative with respect to terminal B. In many metals and semiconductors this is the case, but in others the sign is reversed. The so-called anomolous Hall effect (reversal of sign in some materials) was not understood until the advent of Wilson's band theory of solids and semiconductors. In the light of this theory, N-type samples give the correct sign since conduction is by free electrons in the upper band but P-type samples give the reverse sign as conduction is by holes (equivalent to an electron with a positive charge) in the lower filled band.

The number n of free electrons or holes per cubic centimeter in semiconductors can be deduced from Hall measurements because the theory shows that

$$n=\pm 3\pi/8eR \tag{4}$$

where R is the Hall constant in centimeters cubed per coulomb, e is the electronic charge (1.59×10^{-19} coulomb), the minus sign is for electrons, and the plus sign for holes. Putting in the values of the constants we find that n is equal to $7.4\times10^{+18}$ divided by R. Hall measurements on the silicon samples C and D of Figure 4 at room temperature gave R values of $+6.5$ and $+0.5$ centimeter cubed per coulomb respectively, which indicates 1.1×10^{18} and 1.5×10^{19} holes per cubic centimeter. Although the impurity of sample C is unknown, that in sample D is 3 boron atoms for each 10,000 silicon atoms. As there are 5.2×10^{22} silicon atoms per cubic centimeter, this means that 1.7×10^{18} atoms of boron are present in this sample and that each boron produces approximately one hole.

The conductivity σ of an electrical conductor is given by

$$\sigma=nev \tag{5}$$

where n is the number of current carriers per cubic centimeter, e is their charge, and v their mobility in centimeters per second per volt per centimeter. Combining equations 4 and 5 we see that the mobility of the holes or electrons in a semiconductor is

$$v=\frac{8R\sigma}{3\pi}$$
$$=0.85R/\rho \tag{6}$$

The mobilities of the holes in silicon samples C and D at room temperature are, respectively, 55 and 33 centimeters per second per volt per centimeter. In intrinsic semiconductors where electrons and holes are both present at the same time, the Hall coefficient is[3]

$$R=-\frac{3\pi(n_1C^2-n_2)}{8e(n_1C+n_2)^2} \tag{7}$$

where n_1 is the electron density, n_2 the hole density, and C the ratio of the electron mobility to the hole mobility. As C is generally greater than one, intrinsic semiconductors show the negative sign.

The value of the mean free path of the current carriers is shown from the theory to be

$$l=\frac{2\times10^{-7}R(2\pi mkT)^{1/2}}{\pi e\rho} \tag{8}$$

where l is the mean free path in centimeters, M is the mass of the carrier ($m=9\times10^{-28}$ grams for electrons and is assumed to be the same for holes), and the remainder of the constants are as previously defined. Substituting in these values we see that

$$l=3.5\times10^{-10}T^{1/2}R/\rho \tag{9}$$

At room temperature the mean free paths of silicon samples C and D are, respectively, 4×10^{-7} and 2.3×10^{-7} centimeter. These are approximately 10 times greater than the lattice constant of silicon which is 5.4×10^{-8} centimeter.

The Thermoelectric Effect

When a semiconductor is connected between two metal wires as shown in Figure 7, a thermoelectric voltage is produced when the junctions are at different temperatures. The sign of the potential is dependent on whether the semiconductor is N- or P-type, the polarity being as shown in the figure. Intrinsic semiconductors give the same sign as N-type. The thermoelectric power for some semiconductors may be as high as one millivolt per degree centigrade, which is greater than that obtained from most metal thermo-junctions by a factor of 200. For pure hole or pure electron conduction the magnitude of the thermoelectric power Q in volts per degree centigrade difference in temperature between the junctions is[10]

$$Q=\frac{1}{e}\left[\log_e n/T^{3/2}-\frac{\log_e 2(2\pi mk)^{3/2}}{h^3}\right] \tag{10}$$

Putting in the appropriate values for the constants we see that

$$Q=6.3\times10^{-4}-8.6\times10^{-5}\log_e RT^{3/2} \tag{11}$$

Reference to the original paper should be made for a treatment of simultaneous electron and hole conduction.[10] Experimental determinations of the thermoelectric powers in silicon samples C and D at room temperature gave 0.92 and 0.44 millivolt per degree centigrade, respectively.

Rectification

When a metal point is placed against an impurity semiconductor as shown in Figure 8, the combination has a nonlinear current versus voltage characteristic and acts as a rectifier. For a P-type sample the current is large when the semiconductor is made positive and the metal point is negative, but is small when these polarities are reversed. For an N-type sample the sign of the effect is reversed so that the current is large when the semiconductor is negative. The plot in Figure 8 was obtained with a tungsten point pressed against silicon sample D which, according to the Hall measurements described, is P-type.

It is impractical within the scope of this paper to give a thorough exposition of rectifying action; however, the following simplified description will convey some of the general features of the theory.[11] Electrons which are thermally excited from the filled band to the acceptor impurity levels produce positive holes in the filled band and charge the acceptor centers negatively. The positive holes in the contact area drift away, thus leaving next

to the metal a negatively charged barrier layer from 10^{-4} to 10^{-4} centimeter in thickness. This barrier layer is a region of high resistivity so that when an external voltage is applied between the metal point and the back electrode, almost the entire drop is across the layer. If the external voltage is poled to make the semiconductor negative, the barrier layer increases in thickness and the resistance goes up. If the semiconductor is made positive the barrier layer becomes thinner and disappears entirely for a sufficiently high applied voltage. This is the direction of low resistance and high current. The case of an N-type semiconductor in contact with a metal is analogous. When electrons are thermally excited from donator levels to the conduction band, the donator levels are left positively charged. Electrons are depleted from the boundary layer, leaving an excess of positively charged donators. A positive external voltage applied to the semiconductor increases the thickness of the barrier and a negative voltage decreases the thickness, thereby permitting a large flow of current.

Thermistors

Thermistors, or *therm*ally sensitive re*sistors*, are circuit elements made of semiconducting materials whose electrical resistances vary rapidly with temperature.[13] The semiconducting materials used in the construction of thermistors include sintered mixtures of nickel oxide (NiO), manganese oxide (Mn_2O_3), and cobalt oxide (Co_2O_3). Figure 9 is a plot of log ρ versus $1/T$ for two compositions which have been extensively used to date. Curve A is for a binary mixture of manganese and nickel oxides and curve B is for a ternary mixture of manganese, nickel and cobalt oxides. These semiconducting materials are unique in that small changes in their composition and impurity content have relatively little effect on their electrical characteristics. This is a particularly useful property as it permits the large scale manufacture of a reproducible product.

The specific resistances at room temperature of the materials A and B are 250 and 2,000 ohm-centimeters respectively, and the corresponding values of E as calculated by equation 1 are 0.68 and 0.60 electron volts. It must be pointed out, however, that the energy band picture of solids is not applicable to these thermistor materials as each of the ingredient oxides have partially filled conduction bands like the metals of Figure 2D and therefore, according to the band theory, should be metallic conductors. This fundamental discrepancy was first pointed out by De-Boer and Verwey.[13] Although these authors have derived a theory different from that of Wilson to explain the electrical properties of this class of materials, it will not be discussed here.

Conclusion

The band theory of solids is capable of explaining such fundamental properties of electronic semiconductors as

(1). The dependency of specific resistance on impurity content.

(2). The negative temperature coefficient of resistance.

(3). The sign of the Hall and thermoelectric effects.

(4). The direction of rectification.

Measurements of the specific resistance and the Hall constant enable one to calculate the density, mobility, and mean free path of the electric carriers as a function of temperature and impurity.

A 3,000 Horsepower Diesel-Electric Locomotive for the Seaboard Air Line Railway

D. R. STAPLES
NONMEMBER AIEE

T. L. WEYBREW
NONMEMBER AIEE

C. A. ATWELL
MEMBER AIEE

A 3,000-horsepower Diesel-electric locomotive has been built recently by the Baldwin Locomotive Works and Westinghouse Electric Corporation for the Seaboard Air Line Railway. This locomotive is the largest and most powerful Diesel-electric locomotive which has ever been built in a single unit.

The purpose of this paper is to describe certain features of this locomotive and discuss their advantages over existing types of locomotives.

General Description

The locomotive is of the articulated truck type, having two main trucks and two swivel trucks, one at each end. Each of the main trucks has four axles, each equipped with a traction motor. The main-truck frame castings extend to the ends of the locomotive and carry the couplers for pulling the train. The two main truck frames are connected at the center of the locomotive by means of a flexible hinge. The two swivel trucks have two axles each and are located at the ends of the locomotive. They are connected to the main truck frames by center pins.

The locomotive cab structure is of welded construction, made of welded plates and structural members. It includes a truss at each side of the locomotive, built up of welded structural shapes. It contains the operating compartment and the equipment compartments separated by partitions. It is supported by the main trucks on center pins and spring plunger-type side bearings.

The power plant consists of two 1,500-horsepower Diesel engines. The engine is the 4-cycle type having eight cylinders in line and is equipped with an exhaust gas-type Buchi supercharger. The rated speed is 625 rpm. Each engine drives a direct-connected generator. Each generator furnishes power to the four traction motors mounted in the truck directly below each power unit.

Features of Locomotive

A locomotive of this type has many advantages which are not available in other types of Diesel-electric locomotives.

As mentioned above, the main truck frames carry the couplers for hauling the train. Also, these main truck frames are connected at the center of the locomotive. Because of this arrangement, the stresses resulting from pulling and bumping the train are absorbed by the main trucks and are not transmitted to the cab structure. The truck frames are very heavy cast steel structures and the stresses do not produce high deflections. The cab structure, however is of light construction relative to the truck frames, and in locomotives in which the pulling and bumping stresses are transmitted to the cab there will be much greater deflection.

The tracking qualities of this type of locomotive are recognized to be of the best. Many of the electric locomotives operating in this country have a similar truck arrangement. These electric locomotives have been recognized as having superior riding and tracking qualities. Good tracking reduces the blows and stresses on the rails and the maintenance required on the road bed.

Resulting from the large number of axles, the weight per axle is extremely low. On this locomotive, the weight per axle is approximately 50,000 pounds, which is very low for a locomotive of this size and capacity. Low weight per axle is very desirable in order to reduce stresses on the rails particularly at high speeds. Low weight per axle also reduces track maintenance.

The large number of axles also permits the application of eight traction motors. This results in a universal locomotive which can be used either in high-speed passenger service or heavy freight service in mountainous territory, by simply changing the traction motor gearing. For example, when this locomotive is equipped with gearing for heavy freight service, the tractive effort at the continuous rating of the electrical equipment is 85,600 pounds with a maximum locomotive speed of 65 miles per hour. Gearing also can be supplied which will result in a maximum speed of 120 miles per hour and a continuous rating of 44,000 pounds. Intermediate gearing between the above limits can be supplied also. The foregoing indicates the wide range of service for which this locomotive is suitable.

In this type of running gear, there is practically no transfer of weight from one axle to other axles when starting a heavy train. This permits each axle to develop its full adhesive tractive effort and results in the locomotive's developing the maximum tractive effort for starting the train. On some types of locomotives particularly those having short 2-axle trucks and short over-all length there is a considerable tendency to shift weight from one axle to the next axle. This is mainly because of the moment set up by the pull of the train at the coupler. This reduction in weight on some axles will decrease the tractive effort which these axles can exert and thus decrease the total tractive effort of the locomotive.

Paper 47-36, recommended by the AIEE committee on land transportation for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted November 13, 1946; made available for printing December 9, 1946

D. R. Staples is with the Baldwin Locomotive Works, Eddystone, Pa. T. L. Weybrew and C. A. Atwell both are affiliated with Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 1. The 3,000-horsepower Diesel-electric locomotive built for Seaboard Air Line Railway by Baldwin-Westinghouse

Figure 2. The 1,500-horsepower power plant undergoing load test

The water and fuel oil tanks are located in the base of the cab structure. This permits the application of very large capacity tanks. This locomotive is provided with fuel tank capacity of 3,500 gallons and water capacity of 2,500 gallons. These are very large capacities and fulfill the requirements of practically any railroad. However, if the need should arise, this type of design permits the application of larger tanks. The fuel oil tanks, being located in the cab frame, are protected from the roadbed by the main trucks. This protects the fuel oil tanks from damage resulting from minor accidents and articles thrown up from the roadbed. In several cases, where the fuel oil tanks have been located underneath the locomotive, minor accidents have punctured the fuel oil tanks with resultant serious damage from fire.

This type of locomotive permits arranging the equipment in the cab so that the train heating boiler can be located adjacent to the operating compartment. In this location, the fireman can control and observe the operation of the train heating boiler without leaving his operating position.

The arrangement of the locomotive permits connecting two 3,000-horsepower locomotive units to obtain a single unit 6,000-horsepower locomotive. The running gears of the two 3,000-horsepower units can be connected with a permanent drawbar. The cabs of the two units can be connected with any of the usual type of flexible connections.

This locomotive is the shortest 3,000-horsepower unit yet available. Expressed in other words, the ratio of horsepower to unit length of locomotive is the highest of any locomotive yet built. A locomotive of minimum length has many advantages to a railroad, for example, ability to use existing turn tables and shop facilities, and to occupy a minimum length of station platforms.

Generating Unit

The generator is mounted on the Diesel engine bed which, in turn, is supported resiliently on the locomotive frame. The rotor is bolted to the flanged end of the engine crankshaft and is supported by the engine main bearing and the single generator bearing at the commutator end. The generator shaft extends beyond the bearing and is fitted with a pulley and Vee-belt drive for the exciter-generator unit mounted on top of the main generator. The air compressor is driven also by the generator shaft extension through a flexible coupling. The engine turbocharger is mounted on top of the main generator to the left of the exciter-generator unit.

The generator frame is rolled from plate and butt-welded to form the barrel. The bearing and brush holder support is formed by a plate welded into the barrel. This method of construction is simple and produces a strong rigid frame. It is lighter than the more common type with a bolted-on bearing support. The roller bearing is carried in a cartridge bolted to the end plate. This cartridge need not be disassembled to remove the rotor from the frame. The cartridge is opened only when necessary to inspect and repair the bearing itself. The bearing is of the double spherical self-aligning type. Ample labyrinths are provided in the inner and outer caps to prevent the escape of grease from the bearing.

In contrast to the usual side-supported brush holders, on the generator they are supported at the end of the brush box. The space around the commutator is less obstructed, and the brushes are more accessible for inspection and maintenance. Double brush holders are used, having two narrow brushes side by side. Each brush has its own pressure finger. This design results in better contact between the brushes and the commutator than obtained with single wider brushes and reduces commutator maintenance.

The generator operates as a separately excited motor using power from the storage battery to start the Diesel engine. During this time, most Diesel locomotive generators are excited by a series winding on the main poles, which is used only for this purpose. No such series winding is needed on this generator. The main field winding is used instead for excitation during engine starting. The generator is smaller in diameter and lighter because the series field is omitted.

The exciter-generator unit operates at 3.6 times the engine speed and consists of two machines mounted in a single frame

assembly. The shaft with the two rotors is carried on two roller bearings, one of which is a thrust type. A dual fan mounted on the shaft between the two rotors draws air through the two machines and exhausts it radially through openings in the frame at the center of the unit. The exciter portion of the unit is a 6-pole machine, four poles of which have a single winding separately excited from the storage battery. The other two poles have double windings. One of these is self-excited, being connected across the exciter armature. The other is excited separately being connected in series with the main-generator armature. The exciter supplies excitation power to the main generator field. This combination of fields and a careful design of the magnetic section of the exciter produce a generator output voltage which varies inversely with current. Such an output characteristic closely matches the Diesel engine loading requirements. This is known as the Westinghouse differential exciter system. Because the desired voltage characteristics are produced by the exciter, the main generator needs no differential series winding. The space which would be required for this winding and its insulation from the separately excited winding is not needed, and the generator is small and light for its rating when its relatively low speed is considered.

The generator portion of the exciter-generator unit has a capacity of 9 kw and supplies power at 75 volts for lighting, battery charging, and locomotive control circuits. It is a separately excited 4-pole machine. The voltage of this machine is held constant by a voltage regulator for engine speed varying between 250 and 625 rpm.

Traction Motor

The locomotive has eight axle-hung traction motors, four of which are on each locomotive truck. The motor is of the series six-pole type and is ventilated separately. Its power is transmitted by a spur pinion on the motor shaft to the gear on the axle. The motor has a rolled steel barrel with a cast-steel commutator end-housing welded to the barrel to form an integral rigid assembly. The pinion end-housing is fitted to the barrel and bolted in place. This latter housing is removed when disassembling the motor. Access to the commutator and brushes is afforded by two large openings, one on the top and one at the bottom.

The brush holders are the usual railway-motor type except that the brushes are split to form two narrow brushes operating under a single pressure finger. This construction has lengthened the brush life and reduced commutator maintenance.

The bare motor weighs 7,380 pounds complete with gearing and has a rating of 650 horsepower output. On this basis, a very favorable ratio of less than 11.5 pounds per horsepower is obtained. This figure is reduced to less than 10 pounds per horsepower when gearing is eliminated from this comparison. Approximately one-half this horsepower output per motor is required on this locomotive. Hence, long life and low maintenance are expected.

This design of locomotive is intended for slow-speed freight service as well as on higher speed passenger trains. In freight service, high tractive effort is important. The maximum reduction gear ratio includes a 15-tooth pinion which is of conventional design. The pinion is shrunk on the motor shaft and replaced readily when worn. With this gear ratio the motor produces a tractive effort at continuous rating of 10,700 pounds or 85,600 pounds for the locomotive. This is unusually high for a lightweight motor using conventional gearing.

Engine Load Control

The cumulative and opposing fields of the exciter cause the voltage curve produced by the generator to take the shape *C* in Figure 3. This curve is at full speed but only at a definite temperature of the generating units and at a particular setting of the exciter field resistor. Lower equipment temperature causes a higher curve and loads the engine beyond its capacity and pulls down its speed. For any equipment temperature the generator output characteristic is fixed at a certain horsepower. The engine speed may be pulled down by its inability to develop this horsepower for several reasons such as valve or ring leakage, defective injectors, or high intake air temperature. It is desirable to regulate automatically the load on the engine to match closely its power output as shown by curve *B*. This result is obtained by

1. A carbon pile type rheostat called a carbonstat, electrically connected in series with the exciter battery field.
2. A pilot valve mounted on and operated by the governor.
3. A metering valve.

Figure 4. Schematic diagram of engine load control system

Figure 3. Result of engine load control at full engine speed

Figure 5. Blower motors and radiator-fan motor circuits

Figure 6. Engine-speed control system

This system is shown in Figure 4. At light loads, indicated by less than full fuel input demanded by the engine governor, the carbonstat is compressed to its minimum resistance by a spring. When the governor load tends to demand more horsepower than the engine can develop at its full fuel input, an arm on the governor lifts the pilot valve piston, allowing oil under pressure to pass through the metering valve to the carbonstat oil cylinder. The oil pressure compresses the carbonstat spring and reduces the pressure on the carbonpile rheostat, increasing its resistance, decreasing the exciter voltage and the load demand. This sequence continues until the demand matches the engine output. If the locomotive and, hence, the generator load decreases, the governor drops the pilot valve piston, relieving the oil pressure in the carbonstat cylinder, reducing the carbonstat resistance until demand and engine output match again.

The metering valve determines the rate at which the oil can flow into or out of the carbonstat cylinder, and, hence, the rate of loading or unloading of the engine. A rotary type valve gives the desired timing without the use of small passages or chokes.

Curve *B*, Figure 3, was obtained by actual test of one of the power plants on this locomotive and represents the results obtained in service by this engine load control system. The corresponding engine horsepower is shown by curve *E*, plotted on an exaggerating scale. The variation of load in the working range is less than 0.75 per cent, which is beyond the accuracy of the test equipment used. Curves *A* and *D* indicate, respectively,

Figure 7. Connections of main generator and traction motors

the upper and lower limits of the loading system. Wide variation in engine power is permitted, therefore, without overloading or underloading the engine.

Auxiliary Motors

The fans which draw air through the engine-cooling radiators are driven by four vertical series d-c motors, each rating 33 horsepower. The fan is mounted on the armature shaft. The two centrifugal blowers which furnish ventilating air to the traction motors are mounted on the floor at the center of the locomotive. Air is forced through ducts in the underframe and sliding joints to openings in the traction motors. The blowers are also driven by series d-c motors.

Motor drive generally is accepted as preferable to a belt drive from the engine for such auxiliaries, but several types of power supply are favored by various locomotive builders. Most of these systems require an extra generator to supply power to the auxiliary motors. On this locomotive, this power is supplied by the main generator. This arrangement eliminates the extra generator on each power plant, which reduces cost and maintenance. The system efficiency is improved also, because the main generator efficiency is better than that of a smaller machine. The motors are designed to operate two in series so that the windings are more rugged and less likely to break.

The traction motor blowers operate whenever the engines are running so that the motors are ventilated during locomotive coasting and idling periods. The fan motors operate in three different combinations depending on the amount of radiator cooling required. The proper combination is selected automatically by thermostat switches actuated by the temperature of the engine-cooling water. For slow speed operation, the four motors are connected in series. The medium speed is obtained with two motors connected in series, and high speed is obtained by shunting the series field sets one half of full strength.

Figure 3 shows the wide range of generator voltage depending on locomotive speed. The auxiliary motors are designed for full speed operation at 600 generator volts which is the continuous rating point. To prevent motor overload, the field shunt is removed automatically above 600 volts by a relay controlling the *F*4 and *F*5 contactors. This system in conjunction with automatic shutter control regulates the temperature of the engine-cooling water very closely under all conditions of load and ambient temperature and without attention from the engineman.

Engine Speed Control

The control of application of power, more commonly termed, the throttle, is entirely pneumatic. When the locomotive is standing still, the Diesel engines are operating at the idling speed. When the throttle is moved from the idle position to the first running position, the traction motors are connected to the generator and the exciter field is energized with a low value of excitation. At this time, the Diesel engines are operating at the idling speed.

The throttle valve is a pneumatic valve designed so that the pressure in the outlet pipe is directly proportional to the movement of the handle. In the idle position, the outlet pressure is zero. In the first power position, the outlet pressure is seven pounds.

Movement of the throttle valve beyond the first power position operates the exciter field actuator as indicated on Figure 6. Operation of the exciter field actuator increases the pressure on the exciter field carbonstat, thereby increasing the excitation of the exciter. At 21 pounds the exciter receives full excitation, and further movement of the throttle valve operates the engine governor actuator to increase the Diesel engine speed.

This system results in a smooth even rate of power application without jerks or sudden changes. It permits the locomotive to exert full tractive effort for starting the train because it is possible to approach more closely the slipping point of the wheels by applying the power at a uniform rate than is the case when the power is applied in large steps It will be noted from Figure 6 that check valves with chokes and volume reservoirs are supplied in the air line to the actuators. These devices prevent a too rapid increase in rate of applying power which could occur if the operator moved the throttle handle too fast. Such operation tends to produce slipping of the wheels and reduces the tractive effort which the locomotive can develop.

It will be noted also that electric valves are supplied in the air lines. The purpose of these valves is to control wheel slippage. It may be, when starting a heavy train on a slippery rail, that the wheels slip in spite of the best care of the operator to prevent this condition. When wheel slippage occurs, the voltage of the motor geared to these wheels increases rapidly. Electric relays are provided which detect this increase in voltage and operate to close a control circuit. This control circuit energizes the electric valve, thereby shutting off the supply of air and exhausting the air line to the governor actuator. This reduces the engine speed, thereby reducing the amount of power supplied to the traction motors. When the slipping ceases, the electric valve is de-energized, air pressure is applied to the engine governor actuator, and the engine speed builds up to that corresponding to the setting of the throttle valve.

The system of wheel slip control is entirely automatic and requires on action by the operator. When wheel slippage occurs, the power is reduced automatically on the slipping motors. When the slippage ceases, power is reapplied automatically to these motors. With this system, the reduction in power is under control of the Diesel engine governor. This prevents any tendency of the Diesel engine to overspeed, which would be the case if the load were removed quickly by such means as opening the electric circuits. Overspeeding of the Diesel engine is likely to trip the engine overspeed governor, thereby stopping the Diesel engine.

This system of wheel slip control reduces jerks and bumps in the train, ordinarily caused by wheel slippage. The rate at which power is reduced to the traction motors is controlled by limiting the rate at which air is exhausted from the governor actuator. The rate at which power is reapplied to the traction motors is controlled also by the rate at which air is allowed to flow into the governor actuator. The control of air flow results in a smooth even reduction in power followed by a smooth even reapplication of power.

No Transition

The main electric circuits of this locomotive are extremely simple. See Figure 7. Each generator furnishes power to four traction motors. The four traction motors are connected permanently in a series-parallel arrangement. One of the important features of the permanent motor connections is that a perfectly smooth acceleration of the train is obtained. On a locomotive which includes a change from one motor combination to another, it is always necessary to reduce the power when making the transition. This reduction in power coupled with the subsequent reapplication of power results in a jerk throughout the train.

The permanent motor connections make it easier for the engineman to operate the locomotive. Only one lever, the throttle lever, is required for complete control of the power of the locomotive. It is not necessary to reduce power and operate a transition lever at the proper operating point while accelerating the train. On locomotives which require a transition, the engineman must observe the ammeter to determine when operating conditions are correct to make the transition. A transition must be made when the train is accelerating from standstill and when the train is decelerating because of ascending a grade. Failure to make the transition at the correct operating point may result in damage to the electric equipment.

Another benefit of the permanent motor connections is that the electric circuits are much simpler and more easily understood. Also, fewer pieces of electric equipment are required, which results in reduced maintenance expense.

The series-parallel connection of traction motors also stabilizes the electrical transmission when starting a heavy train. If the wheels geared to one traction motor start to slip, the current through the two motors in this circuit decreases. Due to the constant horsepower characteristics of the generator, a reduction in current is accompanied by a rise in voltage. A rise in generator voltage, however, causes a rise in current in the remaining two motors in the parallel circuit. This rise in current limits the rise in generator voltage and stabilizes the electrical conditions.

This locomotive has been in both passenger and freight service for several months and has demonstrated its practical advantages. Its performance has been observed by many railroad men, and their satisfaction has resulted in orders for similar units from several railroads. The Seaboard Air Line Railway also has ordered a number of duplicate units.

Higher Voltage Copper-Oxide Rectifiers

I. R. SMITH
ASSOCIATE AIEE

THE FIRST metallic rectifier to be accepted generally in the United States for industrial and power uses was the copper-oxide rectifier. Such applications for this rectifier began to be made in 1927, and since that time literally millions of these rectifiers have been put in service. The story of the remarkable development of the copper-oxide rectifier has been told many times. Suffice it to say here that the original optimism as to its long life, dependability and suitability for industrial use has long since been justified. So far as life is concerned, it may still truly be said that its life is indefinitely long—there is still no indication that there is any limit to the life of a copper-oxide rectifier that has been properly designed, applied, and used. Figure 1 shows a typical life test curve, covering a period of 15 years of operations. In this curve a preliminary aging period can be observed, followed by a great reduction in the rate of aging so that output remains practically constant for many years.

The earliest examples of these rectifiers were simple stacks of $1^1/_2$ inch diameter cells, sometimes with small radiating fins, which were generally rated at about 3 volts, 1/4 ampere direct current per basic rectifier (single phase bridge). As time went on some increase in these ratings was obtained by means of improving the cooling. Large diameter fins, coupled with metal spacers to get proper fin spacing for maximum cooling effect, brought the rating in a single phase bridge up to 4.5-volt 1/2-ampere d-c output per cell. An additional increase resulted from the use of forced cooling, using small propellor type fans, which permitted outputs of 5 volts, 1 ampere per cell, again from a single phase bridge. At this point, however, a limit was reached. Unless one were willing to go to the impracticable expense of refrigeration, there was nothing more that could be done to increase the output ratings.

Rectifier ratings are based on the losses which have to be dissipated and the ability of the rectifier structure to get rid of them without reaching a temperature at which the rectifier may become unstable or suffer excessive deterioration in characteristics. So when the structure of the rectifier has been developed to its maximum heat dissipation capability, further improvement can only come by reduction in losses, or in other words, by improvement in rectifier characteristics.

Research into the problem of improving the quality of the copper-oxide rectifier has been going on ever since its discovery in 1921. It is fairly general knowledge by now that the process of making a copper-oxide rectifier involves the use of a particular type of high purity copper, which is oxidized at a temperature not far from its melting point, subsequently annealed at an intermediate temperature, and then quenched in water. The process is relatively simple on the surface, although the most careful control is required at all points to get consistently good results. When carried out properly, the process results in a cell with a thin coating of cuprous oxide, tightly adherent to the copper base. The copper-cuprous oxide combination made in this way is inherently a rectifier, requiring no additional operation, such as forming, to enhance its rectifying characteristics.

Figure 3. Rear view of power cubicle, radio station *KDKA*, showing forced-cooled copper-oxide stacks at rear

The research programs that were laid out embraced all phases of the problem. Most effort however was directed toward the process itself, with the chief aim being to produce improvement in the reverse resistance which would allow higher voltage ratings, since this was felt to be the most fruitful field in which to work.

The first tangible result of this work then was a new process of manufacture known as the vacuum-preanneal process. In this process the copper blanks, after the initial cleaning step, were placed in a vacuum furnace and maintained at a high temperature and a relatively high vacuum for a considerable period. Then they were put through the normal oxidation, annealing and quenching steps, as before.

This process produced cells having roughly four times the reverse resistance of the standard cells, with forward resistance approximately twice that of the standard cell. This was the sort of change needed to permit operation at higher cell voltages. It was found by appropriate life tests, that these cells could be safely operated at the same current as the standard cells, and at twice the voltage. Maximum ratings were obtained with forced draft, for which condition an operating rating of 20 volts direct current per basic rectifier (three phase bridge) was reached.

Production of these cells began on a small scale in 1939. The first installation in the field was made at radio station *KDKA*, at Saxonburg, Pa., in June 1939. This was a fan-cooled rectifier designed to deliver continuously 3,000 volts, 1.4 amperes direct current. It was a 3-phase bridge-connected rectifier, in which the cells were operated at 20 volts, 0.7 ampere direct current each.

Performance of the rectifier was so satisfactory that in the new *KDKA* station then being built at Allison Park, Pa., all of the rectifiers up to 3,000 volts direct current were of the new higher voltage copper oxide cells. Figure 2 shows the type of unit construction developed for this installation and others like it, while

Figure 4. Rear view of type *TBM-10* Navy power pack, with forced-cooled copper-oxide stacks

Figure 3 shows an inside view of a power cubicle at *KDKA*, in which two 3,000-volt rectifiers can be seen mounted in an air duct in the floor. Air is blown up through the stacks and exhausted at the top of the cubicle.

Because all of the equipment at this station was forced-air cooled, the requirement of forced air cooling for the copper-oxide rectifiers did not add to the ventilating expense, in view of the relatively small amount of air required and the low pressure drop through the units.

The satisfactory performance of these

Figure 5. Volt-ampere curves, type *S* and type *Q* copper-oxide rectifier cells

rectifiers resulted in their being adopted as standard in all Westinghouse commercial transmitters above 5 kw. The volume of production of these transmitters was such that it absorbed the entire available production of the vacuum-preannealed or type *H* cells, up to the time when the war put an end temporarily to the manufacture of commercial radio equipment.

The war however brought on a great demand for all types of radio equipment among the more important of which were the Navy shore and ship transmitters of all types. These were normally powered by multiple voltage motor-generator sets, in which a serious production bottleneck quickly developed. Fortunately the type *H* Rectox units in the various commercial transmitters had by this time piled up a very successful performance record, so that it was felt to be proper to suggest the copper-oxide rectifier to the navy as an alternate source of power. A sample power pack was submitted and approved, and a program adopted of using rectifier power packs for shore stations, thus freeing the motor-generator set production for ship use. Nearly 40,000 stacks containing some $3^1/_2$ million cells were supplied for this program, requiring a shop set-up with eight vacuum furnaces at the peak of production.

Figure 4 shows a rear view of one of the power packs developed for Navy use. This was known as the type *TBM-10*, and contained four copper-oxide rectifiers with outputs of 3,000 volts, 0.35 ampere, 2,000 volts, 0.75 ampere, 1,000 volts, 0.1 ampere and 275 volts, 0.6 ampere, all assembled in the same block of stacks and cooled by a single fan.

During this time continued research was going on, spurred by the fact that the

vacuum process was proving rather difficult to control for shop use. This culminated in a new, far simpler process, in which the vacuum step was eliminated. This process, known as the type Q process, produced cells with initial quality equal to the type H cell, but with greater uniformity of product and superior aging characteristics.

This process is now the standard for producing the higher voltage type of Rectox cells.

The type Q cell has a forward volt-ampere curve as shown in Figure 5, where also is shown a typical curve for the standard or type S cell for comparison. It will be observed that at 0.5 ampere, for example the type Q cell has about twice the voltage drop as does the type S standard cell.

In the reverse direction, typical curves also are shown in Figure 5. Here the type Q cell may be seen to have about four times the resistance of the type S at a given voltage, say 15 volts.

The same output voltage ratings then were adopted for the type Q cell as for the type H, namely double the ratings of the standard cells for any given constructions, with the current ratings being the same as for the type S. The over-all voltage regulation of the type S and Q rectifiers is about the same, since the higher resistance of the type Q cell is offset by the smaller number of cells required for a given voltage output.

Typical efficiency curves are shown in Figure 6, again comparing the standard to the higher voltage type. There will be observed a slight improvement in efficiency resulting from the improved reverse characteristic.

The forward aging of the two types is identical. Aging in the forward direction for the copper-oxide rectifier, it will be remembered, is strictly a function of the temperature of the stack. At any normal temperature, then, the change in resistance for both types will follow the same curve.

Applications of these higher voltage cells have so far been largely in the radio-broadcasting field, where large numbers of stacks are operating at voltages up to 3,000 volts direct current. In this field they have shown outstanding advantages, such as simplicity of control, instant starting, elimination of any warm-up period, elimination of filament windings, and particularly freedom from maintenance and unpredictable failures. The original rectifiers which were installed in November 1939 at *KDKA*, for example, have completed seven years of service at 18 hours per day, without failure. In fact the forward aging so far has been so slight as not to have been noticed by the station operators.

Figure 7. A totally enclosed 75-kv 0.25-ampere d-c forced-cooled copper-oxide rectifier

Figure 6. Comparative efficiencies, type S and type Q copper-oxide rectifiers, stacks only

Another interesting application for the higher voltage cells was a 70-kv 1/4-ampere d-c totally enclosed rectifier, used in fly ash precipitation. This unit, shown in Figure 7, with covers removed, was also a forced-cooled rectifier, a recirculating system with heat exchanger being used.

The type Q cell can of course be used in nearly all ordinary rectifier applications. The tendency has been to use it for the higher voltage work, where the greatest savings can be shown, so that it is in these applications that the bulk of the production so far has been used.

This development is another indication that the metallic rectifier, copper-oxide type, is still expanding its field of usefulness. Each increase in output rating widens the range of application. What the future may bring it is still too early to say, as there is no indication that the copper-oxide rectifier has reached a limit in output ratings beyond which there can be no further increase.

Developments in Diesel-Electric Traction-Generator Excitation Control Systems

C. A. BRANCKE
ASSOCIATE AIEE

G. M. ADAMS
ASSOCIATE AIEE

Synopsis: The introductory review covers the major inherent and external regulating excitation systems which have been developed for use on Diesel-electric locomotives. A recently developed amplidyne excitation system using saturable core reactors and selenium rectifiers to obtain definite generator field and armature current limits is described in detail. Used in conjunction with a speed sensitive power plant regulator it provides complete and flexible engine control over its entire operating range of speed and power. Maximum flexibility of motive power is provided by safe and complete remote control which permits operating several locomotive units in multiple.

SEVERAL different excitation systems have been used during the past 35 to 40 years on gas and Diesel-electric cars and locomotives. Most of these have been of the inherent regulating type, depending upon built-in generator or exciter characteristics. Very few have been externally controlled, and most of these have been limited to applications using relatively large power plants.

Inherent Regulating Systems

The earliest excitation system, as used on the first gas-electric rail cars, consisted of a shunt wound generator with a self-excited exciter. Output was controlled by manually changing engine speed and generator field resistance independently. This system was used with apparent success over a period of approximately ten years when this activity was interrupted by World War I.

The next system used on gas-electric rail cars consisted of a generator with two shunt field windings, both of which were energized from a separately (battery) excited exciter. One generator field winding was connected directly across the exciter and the other was connected in series with the control battery, and thus furnished excitation only when the exciter voltage was above battery voltage. The exciter also had a series differential field winding which carried generator armature current, thus producing a drooping generator characteristic. This resulted in a system which was very sensitive to engine speed. It would reduce load rapidly with slight reductions in speed, thus always balancing near rated engine speed regardless of temperature or engine changes.

The excitation system used on the earliest Diesel-electric switching locomotives was similar to this, differing only by elimination of the battery field and by winding the series differential field on the traction generator instead of the exciter. These changes both were made because of battery charging considerations, as considerably more operation at reduced engine speeds is obtained inherently on a switching locomotive. The battery was charged through a carbon pile regulator from the exciter.

The auxiliary requirements on Diesel-electric switchers soon led to the adoption of a constant voltage supply for battery charging, air compressor, traction blowers, and radiator fan motors, at which time the exciter was eliminated. The traction generator then was changed to a combination of self and separate excitation, still retaining the series differential field. While the speed-loading characteristic was not quite as good as that obtained by using a separate exciter, it proved to be satisfactory for this type of service.

Still another arrangement was introduced at about this same time for use on lightweight low-powered locomotives, which is still used extensively today. This consisted of a self-excited shunt generator with an auxiliary (battery excited) "teaser" field winding (which was used only during starting at low generator voltages). This system depends upon an appreciable amount of engine stalling to obtain suitable generator characteristics and engine utilization. In the present-day applications the teaser field has been eliminated and equivalent results obtained by interconnecting the battery in the self-excited field circuit through suitable resistors.

One of the most popular inherent regulating excitation systems is that using the "split-pole" exciter. This consists of a conventional shunt generator but the main poles of the exciter are "split" so that the series differential field can be wound on a part of each pole. The shunt

Figure 3. Saturable core reactor showing flux produced by a-c and d-c windings

winding encircles the complete pole, the same as in a conventional machine, and is primarily battery excited although it usually has, in addition, a self-excited connection through relatively high resistance. This results in a generator characteristic which has practically constant kilowatt output over a two to one range in current. It is also highly speed-sensitive and is thus ideally suited for use on Diesel-electric applications.

External Regulating Systems

Although all of the inherent regulating systems have proved very satisfactory they all are limited economically in their application to relatively small power plants. The need for an external load regulating system appears to be in direct proportion to the size of the power plant because this permits using the minimum size generator and still results in maximum permissible output under all conditions, thus reducing initial cost and providing optimum performance. All of our studies along these lines indicated that engine speed was the basic function upon which such a system should be based as this always would result in maximum power output, regardless of variations in temperature, altitude, fuel, or engine ability.

Our first application of this type was on a rail car powered by a 535-horsepower 950-rpm gasoline engine and consisted of a conventional shunt generator which was separately excited from a constant voltage source through a face-plate rheostat. The rheostat arm was driven by a governor actuated servo motor, thus regulating the excitation as a function of engine speed. These controls were effective over the entire engine speed range and included a variable fuel limit, thereby limiting engine torque to safe values at all speeds.

Shortly after this we made a similar application on a 115-ton switching locomotive with an 825-horsepower 500-rpm Diesel engine. Generator characteristics for this locomotive are shown in Figure 1. This locomotive also used a separately excited shunt generator and a face-plate rheostat. The rheostat arm, however, was electrically controlled by a contacting mechanism or switch attached to the engine governor output shaft so as to respond to very minute changes in engine speed. This "speed" switch controlled the magnet valves of a balanced air engine which operated the rheostat arm. Quick response was obtained when increasing excitation by momentarily connecting an auxiliary contact brush on the rheostat arm, which was positioned several bars in advance of the main contact brush. Stability was obtained by means of an anticipating solenoid on the speed switch, which was energized only when the high speed contact was closed. This solenoid opposed the governor spindle movement and temporarily displaced it sufficiently to cause premature opening of the high speed contact. This permitted rapid movement of the rheostat arm while approaching its ultimate position after which a notching effect was obtained until the final balancing point was reached. Variable fuel limit was obtained by repositioning the stationary contacts for each engine operating speed, thus forcing the electric controls to operate at proper fuel setting for each operating speed. Automatic traction motor transition was provided, the forward transitions being made whenever maximum generator excitation was obtained, as indicated by the rheostat arm position. Because no differential field was used, the generator volt-ampere characteristics for all field settings were very flat, with the voltage decreasing very slightly with increasing current, governed entirely by internal resistance and armature reaction. There was therefore no inherent limitation in generator current. Wheel slipping provided the necessary protection against excessive generator current when the motors were in series and a current relay was provided to initiate backward motor transitions whenever maximum generator current was obtained with the traction motors in parallel.

Amplidyne Excitation System

A recently developed system uses a shunt generator and an amplidyne exciter. The exciter, together with its associated control equipment, always furnishes the proper current for the shunt field of the traction generator. This system, in conjunction with the power plant regulator, automatically regulates the excitation to provide optimum locomotive performance without exceeding

1. Maximum available engine power.
2. Maximum traction generator load current.
3. Maximum traction generator field current.

The limitations imposed by the engine are obvious. Generator armature current must be limited to prevent overheating or excessive sparking. Several load current limit settings are desirable to provide the operator with controlled tractive effort for proper locomotive operation. The generator field current is limited to permit using minimum field structure and to limit the maximum generator voltage. Figure 2 shows the resulting generator characteristics at rated engine speed when observing these limitations.

Saturable Core Reactors

A brief review of the characteristics of a saturable core reactor probably will be helpful before attempting to describe the complete system.

The reactors used in this system have a 3-legged iron core with series connected a-c windings on the two outer legs, and one or more d-c windings on the center leg as illustrated by the upper portion of Figure 3. The a-c windings create alternating flux in the outer part of the core only, whereas the d-c windings create flux in all parts of the core, including the center leg, as shown in the lower portion of Figure 3. The d-c windings are used to saturate the core to varying degrees. Any saturation of the core reduces the amount of a-c flux produced by a given alternating current. As the alternating voltage across the reactor will be proportional

to the a-c flux, the voltage across the a-c winding will decrease as the d-c flux increases, assuming constant alternating current in the windings.

Basic Regulating Circuit

The basic regulating circuit is shown in Figure 4 and consists of two saturable core reactors *XA* and *XB*, with their a-c windings connected in series across a constant alternating voltage supply. The d-c winding of reactor *XB* is connected in series with a calibrating resistor across a constant direct voltage supply. The current to be controlled, *I*, is fed through the d-c winding of reactor *XA*. When *I* is zero, there is no d-c flux in reactor *XA*, whereas reactor *XB* has a definite preset d-c flux. Because the sum of the alternating voltages is constant, we then will have more alternating voltage on *XA* than on *XB* As current *I* increases, the alternating voltage on *XA* decreases, whereas the alternating voltage on *XB* increases. When current *I* increases to the point where the d-c flux in reactor *XA* equals that in *XB*, the alternating voltages will be equal. As *I* increases beyond this point, the alternating voltage across *XA* continues to decrease and the alternating voltage across *XB* continues to increase. Thus for any given setting of the calibrating resistor, the alternating voltage across reactor *XB* is always proportional to direct current *I* in reactor *XA*. This voltage is rectified by means of a full wave selenium rectifier and fed into the exciter field control circuit to regulate excitation as a function of any desired current *I*.

It also should be noted that this arrangement permits control of the excitation circuit without any electric connection between it and the controlling function. It is thus possible to obtain a regulating force for use in the relatively low voltage excitation system which is proportional to any desired current *I*, regardless of its voltage, merely by providing suitable insulation on the d-c winding of reactor *XA*.

Basic Excitation System

Figure 5 shows the basic excitation system for a typical locomotive application with the approximate voltages indicated for various parts of the circuit. A 400-cycle 115-volt alternator, driven by a 74-volt d-c motor, is used to energize the primary winding of transformer *T1*. This transformer has three secondary windings; one is wound for 25 volts and the others for 55 volts each. The 25-volt winding is connected to full wave selenium rectifier *R1*, which furnishes 20-volt d-c power supply to load control potentiometer *125* and its series connected resistor *120*. Filter reactor *164* is inserted in the d-c feed circuit to reduce the a-c ripple. The output of potentiometer *125* is connected to amplidyne field *F1-F2* and its series connected resistor *152*. This resistor has approximately four times the ohmic value of field *F1-F2*. Thus the maximum field voltage that ever can be obtained is only 20 per cent of the d-c supply, or 4 volts. Under this condition the voltage drop across resistor *152* is 80 per cent of the d-c supply, or 16 volts.

The amplidyne exciter field resistor circuit was designed to obtain a maximum exciter field current equivalent to twice that normally required for any steady state full output condition, thereby providing rapid generator response whenever increased excitation is required. This "forcing" action is even greater at all other points of operation on the generator characteristic where lesser excitation is normally required. The field current therefore always is limited under full output steady state conditions to 50 per cent or less of the maximum obtainable. Thus the field voltage is never more than two volts under any steady state full load condition, and the voltage across resistor *152* is never less than 18 volts. With this field circuit arrangement it can be seen that if the voltage drop across resistor *152* could be increased by some external means to 20 volts, the exciter field voltage would be reduced to zero. It is therefore only necessary to increase the voltage across resistor *152* approximately 10 per cent to obtain 100 per cent reduction in excitation.

Such a high rate of response was made possible by the use of the amplidyne exciter and its previously developed stabilizing circuit. This consists of an additional winding (not shown in Figure 5) connected in series with a capacitor across its output circuit, and is thus only effective during a change in exciter voltage. Its polarity is such as always to oppose any change in exciter voltage, whether it be increasing or decreasing. The opposing action is also proportional to the rate of change and thus always provides proper stabilizing action.

Because the input to amplidyne field *F1-F2* is but one watt for steady state full output conditions, very low energy control devices, inherently small and lightweight, can be used. All of the static devices, consisting of a transformer, reactors, rectifiers, and resistors, are assembled in one group on the panel shown in Figure 6.

Generator Load Current Limit

The a-c windings of saturable core reactors *X1* and *X2* are connected in series across one of the 55-volt secondary windings of transformer *T1*. The d-c winding of reactor *X2* is connected in series with its calibrating resistor *156* across the 74-volt locomotive battery, thus establishing its amount of saturation. The d-c winding of reactor *X1* is connected in series with resistor *116* across the commutating pole field of the main generator. Resistor *116* provides temperature compensation. It is designed to heat up and increase its resistance at approximately the same rate as the generator commutating pole field. The current flowing through the d-c winding of reactor *X1* is therefore proportional to generator armature current. With no current flowing in the generator, there will be no current in the d-c winding of reactor *X1* and hence minimum saturation. Having previously set the saturation in reactor *X2* we then obtain minimum voltage across the a-c windings of reactor *X2* and connected rectifier *R3*. The output voltage of rectifier *R3*, if disconnected from the system, would be far below that being obtained across resistor *152*, to which it is normally connected. Rectifier *R3*, however, blocks any reversal of current; hence this connection has no effect on the amplidyne field circuit under these conditions. As generator load current builds up, the alternating voltage across *X2* increases and finally reaches a

Figure 4. Basic regulating circuit

Figure 5. Basic excitation circuit

point where the d-c output voltage of rectifier *R3* is just equal to the drop across resistor *152*. Any further increase in generator load current then will increase the d-c output voltage of rectifier *R3*, thus forcing additional current flow through resistor *152* and increasing its voltage. This increase in voltage reduces the voltage across amplidyne field *F1-F2*. This action continues until the amplidyne excitation has been reduced to the point where it is just sufficient to maintain the current flowing in the generator armature. A very sharp cutoff is obtained for, as previously pointed out, only a 10 per cent increase in voltage is required across resistor *152* to reduce amplidyne excitation to zero. Thus, when sufficient current flow is obtained to increase the voltage drop across resistor *152* by one-half volt (less than three per cent), the amplidyne excitation will be reduced to 75 per cent of the maximum ever required for any steady state full output condition. As the a-c voltage across reactor *X2* is proportional to generator load current, it can be seen that less than three per cent increase in load current will be required to obtain 25 per cent reduction in amplidyne excitation. Because the traction generator normally is being operated quite low on its saturation curve whenever load current limit is effective, this slight change in load current will produce approximately the same high percentage change in generator voltage. Thus the generator volt–ampere characteristics are very steep at the high current ends of the curves. This is of particular value on locomotive applications because this always will permit the operator to work very close to the adhesion point without danger of slipping the drivers, regardless of rail condition.

Generator Field Current Limit

The a-c windings of saturable core reactors *X3* and *X4* are connected in series across the other 55-volt secondary winding of transformer *T1*. This pair of reactors, together with rectifier *R2*, regulate the amplidyne excitation as a function of generator field current in exactly the same way as reactors *X1* and *X2*, together with rectifier *R3*, regulate the amplidyne excitation as a function of generator load current. When the generator field current reaches its limit setting, rectifier *R2* starts "spilling" and regulates the amplidyne excitation, thereby providing a ceiling on generator field current. Reactors *X2* and *X4* are exact duplicates. Reactors *X3* is identical with *X1* except that its d-c winding is designed to carry full generator field current but the d-c winding on *X1* only carries a small percentage of the generator load current.

These two limit circuits are entirely independent and have no effect on each other. Therefore, when operating at high load currents, the generator field current is relatively low so that the alternating voltage across reactor *X2* is high (and regulating), whereas that across *X4* is low. This low voltage on *X4* has no effect on the excitation because blocking rectifier *R2* prevents any reversal of current in this circuit. Likewise, when operating at high generator field current, the load current is relatively low and the alternating voltage across *X4* is high (and regulating), and that across *X2* is low. Blocking rectifier *R3* then prevents any reversal of current because of low alternating voltage on *X2*.

Load Control

If only load current and field current limits were provided, we would obtain maximum generator characteristics which would be very flat at the high voltage end, and very steep at the high current end. Under these conditions it would only be possible to utilize full engine output at some one point, without seriously overloading the engine at other points. These two limits therefore are designed to produce generator characteristics which at rated speed over an appreciable range of current, demand more power than the engine can develop. The power plant regulator (which is described in detail in a separate paper[1]) then reduces the excitation as necessary over this range as a function of engine speed. This is accomplished by potentiometer *125*, which reduces the d-c supply voltage to the amplidyne field circuit whenever the generator load demand exceeds engine ability. The composite curve shown in Figure 2 is the result of all three of these "limit" circuits.

Locomotive Application

Almost all Diesel engines can operate successfully over a 3-to-1 speed range. Advantage is taken of this variable speed characteristic to obtain variable power output easily and economically. Standard practice for several years by most manufacturers of Diesel-electric road locomotives has established the use of eight throttle handle notches for obtaining eight different engine operating speeds on units which are operated in multiple. The amplidyne excitation control circuits

Figure 6. Excitation control panel

Figure 7. Generator output curves for all notches

therefore were designed on this same basis in anticipation of probable requests by ultimate customers to operate in multiple with existing locomotives. Thus, while we use but one fixed generator field current limit setting, we have a total of eight different load current limit settings. This, in conjunction with the different engine speeds and fuel limit settings, results in eight different generator output curves as shown in Figure 7. Resistor *156* shown in Figure 5 is commutated to obtain a different current limit setting on each throttle handle notch by remotely controlled relays which also commutate resistors for simultaneously changing the engine speed and fuel limit settings.

The advantages of the load current limit feature can be seen by comparing these curves with those shown in Figure 1. When starting from rest, the generator load consists of the resistance of the traction motors together with connecting cables, and can be represented by the straight line extending from the origin, which is marked "0 mph." When starting the locomotive, the throttle handle is notched out until sufficient current is obtained to develop the tractive effort necessary to start moving the train. As soon as the train starts moving, the equivalent resistance of the generator load increases rapidly because of the counter electromotive force being developed by the traction motors. Thus, with the generator characteristics shown in Figure 1 the load current drops off rapidly as the locomotive starts moving with resultant immediate reduction in tractive effort whereas the load current and tractive effort are maintained nearly constant with generator characteristics shown in Figure 7.

A-C Excitation Source

The alternating voltage developed by the 400-cycle alternator will be affected by variations in locomotive control battery voltage as well as its own temperature and loading. Variations in this a-c supply voltage will cause corresponding variations in the alternating voltage across the saturable reactors. These variations are nullified by providing a d-c supply to the exciter field resistor circuit which varies in exactly the same way. This is the reason for using rectified alternating current fed from the same transformer that supplies the reactors, rather than battery supply for the excitation circuit. With this arrangement the limit settings are changed only slightly by all the variations in a-c supply voltage normally obtained in service, and are not of sufficient magnitude to be of any consequence.

Dynamic Braking

During dynamic braking, all traction motor fields are connected in series across the traction generator and their armatures are connected to the braking resistors which dissipate the energy developed by the motors.[2]

Under this condition the generator output is very low, being practically negligible at top locomotive speed where minimum motor excitation is required, and but 15 to 20 kw at lower speeds where maximum motor excitation is needed. The maximum generator current ever required is approximately one-fourth of that used during motoring, while the maximum voltage is but four to five per cent of maximum motoring voltage. The Diesel engine therefore is operated at idling speed and the traction generator series cranking winding is inserted into the circuit to obtain as much inherent stability as possible. It also must be possible to change the traction motor excitation very gradually to permit obtaining any desired braking rate, up to the maximum, at any locomotive speed. The same rectifiers and reactors are used to control the generator current output during braking as are used during motoring, but the controlling circuits are rearranged because of the lower range in generator armature currents and the necessity of providing fine graduations in current limit settings. This is accomplished by adding a modulating d-c winding to reactor *X1* and connecting it, as well as the d-c winding on reactor *X2*, to a resistor network so arranged that the current limit setting can be changed by varying the potential applied at one point of this circuit. The operator then can adjust the excitation to suit any requirement by varying the potential at this point. This is done by a controlling potentiometer which is operated by the braking control handle. The variable voltage appearing at the brush arm of this potentiometer is applied to one of the control train wires. Simultaneous recalibration of the current limit settings on any number of locomotive units operating in multiple thus is obtained by merely varying the voltage applied to this one train wire. The energy involved is so low that a relatively small potentiometer is only slightly affected by the number of units operating in multiple. Because the amplidyne field current is regulated automatically to maintain a definite generator armature current for each setting of the braking handle, the system is not affected by changes in engine speed or changes in temperature, both of which would seriously upset any Ward-Leonard system.

Conclusions

This latest excitation control system contains several new features which result in improved performance as well as reduced maintenance and higher locomotive availability. These consist of

1. *Engine Protection.* All engine limitations are observed, thus providing reduced torque at reduced speeds and controlling the loading to maintain proper speed on each notch, regardless of changes in temperature, altitude, fuel, or changes in engine ability. It is flexible and readily conformed to suit any reasonable engine speed-torque characteristic. Additional functions can also be readily incorporated; for example, reduction in loading in event of high engine temperatures. These protective features should result in long life and low engine maintenance, together with improved performance.

2. *Generator Protection.* Limiting the maximum load current and the maximum field current greatly reduces the possibility of overheating the generator. The load current limit also limits the commutation duty for which the generator must be designed.

3. *Controlled Tractive Effort.* By providing several different generator load current limit settings, the operator always can obtain the desired tractive effort. This should improve locomotive performance, especially when starting a heavy train. As the excitation is regulated as a function of generator output, this automatically eliminates any variations in this output because of variations in excitation voltage supply, machine temperature, or individual generator characteristics.

4. *Minimum Size and Weight Control Devices.* The amplidyne exciter requires very low energy input, thereby permitting the use of high safety factors in designing and still obtaining unusually small and lightweight devices.

5. *Low Maintenance.* The transformers, reactors, rectifiers, and resistors used in the

limit circuits have no moving parts and thus require minimum maintenance. Being static, the possibility of trouble is reduced greatly, and should result in increased locomotive availability.

Discussion

Lanier Greer (General Electric Company, Erie, Pa.): Since the days of the first gas-electric rail cars and locomotives, the desirability of a power unit control and generator excitation system which would accurately control engine speed and loading regardless of variations in temperature, fuel, altitude and engine ability has been acknowledged. This has become more important with the advent of the Diesel engine and with the increased speed and power of these engines. Inherent regulating systems, although rugged and simple, have been proven to be inadequate for the modern high-speed high-power Diesel engine. This has made it necessary to find an external regulating system which accurately will control and impart the desired characteristics to the engine generator combination. Such a system is described in the paper under discussion and has advantages for each major piece of rotating apparatus. These accrue as simplicity of design, lighter weight, lower initial cost, better performance, and lower maintenance.

The source of power for the Diesel-electric locomotive is the Diesel engine and if it is not properly regulated and protected the maximum amount of work cannot be performed. If the control system of the power unit as a whole is such as to allow the engine to operate under optimum conditions at all times, the best possible performance will be obtained. By accurately controlling speed, loading, and temperature of the engine under all conditions of operation, as is done by the system under discussion, engine maintenance will be kept low, time between overhauls will be increased and engine performance will be improved.

Mechanical power produced by the engine is delivered to the generator which converts it into electric energy. The generator is simplified by accurately controlling the maximum load current to a value which gives adequate starting tractive effort, when applied to the traction motors, and by limiting this current to a definite maximum. This reduces the possibility of excessive sparking due to overload current.

By externally controlling and limiting the field current (maximum voltage on the high voltage end of the engine generator volt ampere curve) the size of the generator field structure is kept to a minimum because a simple single exciting winding can be used on the main poles. This reduces the amount of insulation in the coils and increases the heat transfer coefficient. By keeping the field current constant, from maximum full utilization to maximum locomotive speed, field heating is controlled and damage to the fields from this cause is minimized. Controlled field current (maximum voltage) keeps the peak volts per bar within reasonable limits and reduces generator flashing.

Accurate control of load and field current makes possible the use of a simple salient pole single armature generator over a wider range of power and speed than would be possible otherwise. This simplifies the generator manufacture and reduces the initial cost. A generator without compensating windings is also an advantage to the operator because it is easy to maintain and repair.

The voltage and load current of the generator are supplied to the motors which drive the locomotive. Controlled load current applied to the traction motors protects them from sparking due to overloads. Also controlled field current on the generator gives controlled voltage on the motors and limits the peak volts per bar to a reasonable value which keeps flashing on the motor at a minimum. This reduction in flashing and sparking reduces heating, gives longer life and helps to keep motor maintenance low.

Therefore, a system of power plant regulation used in conjunction with a generator excitation system such as described in the paper by C. A. Brancke and G. M. Adams does these three things for the major pieces of rotating apparatus.

1. Gives better prime mover performance.

2. Makes possible a simpler lighter-weight and smaller traction generator.

3. Keeps the maximum that is demanded from the traction motors to a reasonable value.

These things combined give lower initial cost, better locomotive performance, longer life, lower maintenance and better availability.

Braking Resistors and Control for Diesel-Electric Locomotives

E. F. WEISER
NONMEMBER AIEE

Synopsis: This paper covers the general scheme and performance of a new dynamic braking system for heavy Diesel-electric road locomotives and a description of design features of the newly developed braking resistor unit.

MANY of the new Diesel-electric road locomotives appearing on American railroads are being equipped with dynamic braking. This enables the locomotive to hold back or to stop as well as to accelerate the train. Attractive savings appear in lowered wheel and brake shoe maintenance and faster schedules.

"Grinding to a stop" is a hackneyed literary phrase, but unfortunately it is a correct technical description of conventional railway brakes in action. Replacing brake shoes and worn and cracked wheels represents a major item in car maintenance. The danger of a train running away on long mountain grades because of overheated brakes losing their effectiveness often dictates speed limits as low as 15 miles per hour with frequent stops to cool the brakes. Faster schedules are possible when the locomotive can absorb all or part of the power generated by the descending train.

Figure 1. Control and power connections during dynamic braking

Generating 1,490 kw of power in the crowded interior of a modern locomotive presents a number of engineering problems, and getting rid of a like amount presents another, for a Diesel-electric locomotive cannot return power to an overhead system as an electric locomotive can.

Braking Scheme and Circuits

The general scheme of dynamic braking employs the traction motors as generators with their fields separately excited to provide control (see Figure 1) and a resistor to dissipate the power generated. Excitation of the motors during braking is accomplished by connecting all motor fields in series with the propulsion generator which is capable of supplying the low-voltage, high-current excitation required by the series traction motor fields. The braking can then be controlled by varying a rheostat in the main generator excitation system. Switching equipment is required in the main power circuits to make up the excitation circuit of the motors and connect the traction motor armatures to the braking resistors. Additional switching in the control circuits sets up the main generator excitation and engine speed control circuits.

Interlocked separate controller handles for motoring and braking require the operator only to return the motoring handle to the "off position" and notch up on the brake handle to brake, being careful not to exceed the motor rated current as registered on his instrument panel ammeter.

Figure 1 shows a simplified circuit diagram of the connections during braking. The generator field control system regulates a constant selected output current to the traction motor fields, independent of minor variations in engine speed, motor field coil temperatures and other variables, using the voltage drop through the generator commutating field coils as an indication of current.

Since the adhesion of the locomotive to the rails is sufficient to generate full motor rated current, and therefore torque, the maximum braking rate is determined by the traction motor ratings. On a 3-cab 6,000-horsepower locomotive this fixes the braking horsepower per cab at slightly over 2,000 horsepower, 1,490 kw, due to the transmission losses which aid during braking.

The tractive effort available for braking is shown in Figure 2 for various speeds. Since, during braking the transmission losses are aiding the braking, the braking tractive effort available is actually higher than the motoring effort at the same speed. With dynamic braking, the locomotive with the assistance of the train's rolling friction can brake the train down a grade without assistance from the air brakes at a higher speed than it can pull the train up the same grade.

The requirements for a braking resistor are that it dissipate 1,490 kw of power in as small as possible space in the already crowded cab and that weight and cost be kept to a minimum.

Resistor Design

The functions of the resistor are

1. To convert electric energy into heat.
2. To take the heat away from the locomotive.

An air-cooled, forced-ventilated design was selected for development because of the unavailability of other cooling mediums on Diesel-electric locomotives and

Paper 47-38, recommended by the AIEE committee on land transportation for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted November 12, 1946; made available for printing December 6, 1946.

E. F. Weiser is affiliated with the engineering division of the General Electric Company, Erie, Pa.

Figure 2. Tractive effort versus speed during dynamic braking in a 2,000 horsepower locomotive

because space limitations demanded operation of the resistor elements at an intensity of heat transfer unobtainable with natural convection.

The problems which emerged during development were primarily those of a heat exchanger rather than a resistor. The final design consists of a double ended, axial flow fan and motor unit, diffusers, tunnel type resistor grids, and discharge elbows. Figure 3 shows the components installed in their mounting frame which forms part of the locomotive cab roof. The discharge elbows, not shown, are incorporated in the locomotive cab roof. The assembly pictured is removable as a unit. Its length is 11 feet 2 inches.

Primary consideration was given to maintaining an air path through the system of constant cross section without turns to reduce eddys and velocity head losses in the air stream. The elimination of eddys and unequal air velocities through the bank of resistors is vital to elimination of hot spots in the resistor bank which would limit the intensity at which resistor grids could be operated.

Two factors determine the quantity of air required: the amount of heat to be carried away and the temperature to which the air may be raised. For standard air conditions the following equation gives the approximate relationship of cubic feet per minute, kilowatts, and allowable temperature rise C in degrees centigrade:

$$C = \frac{1750\ (KW)}{CFM}$$

The permissible temperature rise is limited by the temperature that the discharge elbow and the paint on the adjacent cab roof can withstand. Limiting this rise to 100 degrees centigrade fixes the air requirements at approximately 26,000 cubic feet per minute to remove the 1,500 kw of power from the locomotive.

Figure 4. Temperature rise of ribbon and air versus kw input for 2,000 horsepower locomotive resistor

The use of such a volume of air made it inadvisable to draw the resistor cooling air from inside the cab, its inlet louvers and filters being already taxed by the requirements of the engine and the generator and motor ventilation. The location of the resistor over one side aisle between the engine and the outside wall enables it to draw its air directly from the outside, to pass it through the resistors and to discharge it vertically through the cab roof.

The fans require 74 horsepower but by connecting the series-wound fan motor in parallel with a section of the resistor it uses part of the power being dissipated. The motor can thus be connected permanently in parallel with its section of resistor eliminating all danger of control failure. This means that the voltage supplied to the blower motor is proportional to the current in the resistor. However, the combined characteristics of the fan loaded series motor, resistor heat transfer and fan discharge result in a temperature versus power curve for the resistor of the type shown in Figure 4 from which it can be seen that the highest kw input region of the curve results in the highest resistor temperature in spite of the resulting higher fan motor voltage and speed in that region.

The terminus of the curve is the point at which the fan motor reaches its maximum permissible speed, limiting the input to the resistor to the kw which produces this speed. Operation of the resistor at altitudes of 7,500 feet in some mountain passes would result in higher fan motor speed than at sea level due to reduced fan load in the rarified atmosphere. Allowance has been made in selecting the fan speed at normal resistor input, 1,490 kw, to insure against overspeed under adverse conditions. To protect the motor against overspeed, a voltage relay is connected across the motor terminals and is set to operate at maximum permissible motor voltage, flashing a warning light near the operator who must correct the condition by reducing the excessive braking rate.

The motor fan unit, shown in Figure 5, is rated at 26,000 cubic feet per minute at 11 inches of water static pressure at 3,500 rpm. Originally developed as a traction

Figure 3. Assembly of blower, diffusers, and resistors in their mounting frame

Figure 5. Fan and motor unit showing fans and contravanes

motor blower, the unit is extremely compact and light in weight for its output. Its small size makes possible an equally important weight saving in the supporting cab structure. The fans are of axial flow type and use curved stationary entry vanes which direct the entering air at the correct angle for efficiency at the high output pressure.

The conversion of the toroidal section of the air stream from the fan into a square section suitable for the resistor is accomplished in a diffuser pictured in Figure 6. Concentric baffles divide the air from the fan and distribute it over the square outgoing section assuring an equal air velocity to all resistor ribbons and elimination of eddys which would recirculate air through portions of the resistors resulting in hot spots.

Figure 6. Two views of diffuser showing inlet and outlet ends

Grid Units

Sixteen resistor grids, eight at each end of the fan unit, make up the resistor proper. Figure 7 shows a single grid. The frame of the grid, which is of insulating material, encloses the resistor element and forms the duct which confines the cooling air stream when stacked with succeeding units. The mounting lugs form both the electrical and mechanical connections. Removal of any unit can be accomplished by removing two bolts and sliding the unit out without disturbing adjacent units.

Parallel strips of a chromium-aluminum-iron alloy resistance material, connected in series, form the resistor element. Conventional supporting tie rods with their mica insulation were eliminated when tests showed ribbon temperature in in the lee of the tie rod ran just twice that in areas not blanketed by tie rods. This single innovation resulted in a 50 per cent reduction in the ribbon area and resistor cubic volume required at no increase in maximum ribbon temperature. By forming each resistance strip into a shallow V cross section which nests with adjacent strips, sufficient mechanical rigidity was obtained and the increased turbulence in the air stream materially increases the heat transfer from the ribbon to the air stream.

The resistance element is fastened in its frame at only two points, the outgoing terminals. Guide pins at the ends of each strip project into clearance holes in the insulation, frame supporting the resistance strips without restricting their endwise expansion, which amounts to 0.1 inch at 375 degrees centigrade rise. All ribbon buckling forces are thus effectively eliminated and it is possible to space the resistance strips closely, effecting a saving in the cubic space required for the resistors.

The use of rolled strip provides grids far superior to castings in durability and resistance to cracking from vibration. Thin rolled sections also provide greatly increased heat radiating surfaces over that of cast section grids. Each of the 16 units contain 42 strips of resistance material presenting 5,855 square inches of radiating surface to the air stream. Each square inch of surface radiates approximately 17.5 watts per square inch. The connectors brazed between ribbons are of heavy section which conduct heat away from the joint and assure joint temperatures substantially lower than that of the ribbon proper.

The air stream passing through the resistor increases progressively in temperature, volume, and velocity. Each successive grid is thus subjected to a higher ambient air temperature, however, the temperature rise of each grid over that of the air emerging from it is substantially the same for all layers. The maximum temperature is experienced by the last grid and is the sum of the outgoing air temperature and the rise of the ribbon over the air passing it. The temperature difference between the ribbon and the air passing it may be viewed as the potential required to force the heat from the ribbon into the air stream. Thus the more heat being transferred per unit area, the higher the required temperature differential. However, the two major factors reducing this differential are air turbulence and velocity. The use of the nesting V cross section ribbons forces the passing air to change direction and assures turbulence. The effect of velocity is illustrated in Figure 8, the higher the air velocity the lower is the necessary temperature differential.

With a given air flow the velocity can be increased by reducing the cross-sectional area of the resistor tunnel. Increasing the velocity, however, increases the fan pressure required to force the air through the resistor and limits the practical velocity to that corresponding to the available fan pressure. In the resistor designed, the air enters the resistor bank at 4,400 feet per minute and leaves at approximately 6,600 feet per minute after heating and expanding. This exit velocity, which is 75 miles per hour in a vertical direction, effectively removes the heat from the vicinity of the locomotive and all trailing cabs and cars, fulfilling

Figure 7. Tunnel type grid unit

Figure 8. Temperature differential required between ribbon and air for one grid unit at 100 kw input

the second major requirement of the resistor, that of getting rid of the heat.

Conclusions

The design can be summarized as a high-velocity air-colled resistor in which major attention has been given to air flow, heat transfer, and the removal of the heated air from the locomotive.

Incidental features include air intake screens, air velocity actuated shutters to protect the exit end of the resistor from the weather while the resistor is not in use, and drains in the exit elbows. The shutters and drains permit the use of air exits which do not project from the cab roof and thus greatly improve the appearance of the locomotive. Some installations incorporate connections to the resistor which makes it possible to load the engine, for test purposes, through the main generator, which is an invaluable aid to the maintenance shops.

No Discussion

Developments in Control Systems for Diesel-Electric Locomotives

M. D. HENSHAW
NONMEMBER AIEE

Synopsis: In the years 1945 and 1946 we have seen the completed development of new and larger Diesel engines designed specifically for use in main line Diesel-electric locomotives. Application of the larger electric transmission systems required for converting the engine power into tractive effort at the rail has presented new control problems, in the solution of which many new developments in circuits, apparatus, and manufacture have been made.

TWO TYPES of main line locomotives were in manufacture prior to World War II. One of these was a 2,000-horsepower unit frequently used in pairs in passenger service. Each cab included two separate 1,000-horsepower power plants with the generators independently connected to pairs of traction motors on three axle trucks, the center axle being an idler. Duplicate installations were required of mechanically driven air compressors, of the engine water and oil cooling systems, and of the electric auxiliaries and control. Only the master controller, the storage battery, and the air brake system served both power plants in common. No dynamic brake installations had been developed for these units.

A second type appeared in 1940 which utilized a single 1,350-horsepower power plant in each cab. The generator supplied power to four traction motors, of which there were two each on the two axle trucks. No idler axles were used. Dynamic braking was available as a holding brake on long grades. This size locomotive found wide application in freight service in spite of the low power rating which required from three to four coupled cabs to handle the service.

The arrival of new Diesel engines of 1,500- and 2,000-horsepower ratings in 1945 and 1946 greatly broadened the field of application of single power plant per cab locomotives. Improvements in traction motors and generators for these locomotives have produced higher ratings so that in some cases three 1,500-horsepower cabs will perform the same service formerly done by four 1,350-horsepower cabs. In high speed passenger service on most eastern railroads, two 2,000-horsepower cabs suffice and the two power plants involved constitute a distinct saving in fuel, lubrication, and maintenance costs in contrast with the four smaller power plants used on the older type of 2,000-horsepower locomotives.

Although some of the new engines operate at higher speeds than have been used before in main line locomotives of comparable power, the design emphasis was placed on long life with minimum replacement of wearing parts. This in turn has constituted a challenge to the control engineer to produce new standards in handling of these larger power units.

As far as possible, circuits and apparatus have been designed to fit both the 1,500- and 2,000-horsepower units. This is of benefit not only in reducing the first cost, but also in simplifying the maintenance, servicing, and renewal parts problems.

Power Circuits—Motoring

The new single power plant 1,500- and 2,000-horsepower units both employ four series wound traction motors, powered from a single main generator.

Conventional series-parallel and parallel motor connections are used (see Fig-

M. D. HENSHAW is with the engineering division, General Electric Company, Erie, Pa.

Figure 3. Typical generator characteristic for 2,000-horsepower unit

ure 1) with a single step of resistor shunting of the motor fields.

Field shunting is analagous to the overdrive commonly used on some types of automotive vehicles. It extends the range in locomotive speed over which full power can be obtained from the generator within its current and voltage limits.

Formerly applied only in the high speed (parallel) motor connection, field shunting now also is used in the low speed (series-parallel) connection as shown in Figure 2. The locomotive is operated up to a higher speed before transfer to parallel is required, and the parallel connection is established at a lower value of generator current as indicated by the dotted lines. As the limiting current rating in parallel is that of the generator and not that of the motors, the use of the field shunting step in series parallel results in a reduction in generator rating, with resultant savings in weight and size.

Excitation System

One of the chief problems in control for Diesel locomotives is the matching of the generator demand to the load the Diesel engine can carry over the required volt-ampere range.

On early units this was attempted by giving the generator output a hyperbolic pattern, obtained by various schemes of self and separate excitation or in conjunction with special exciters.

The pattern obtained usually was subject to variation from temperature changes in the equipment itself, from battery voltage change, or from misadjustment. None of the schemes recognized any change in engine ability, such as might be caused by faculty fuel injection equipment. When such faults occurred, or when the electric equipment was cold, the engine became overloaded and stalled in speed. This in turn frequently aggravated the condition and contributed to early failures.

As the art advanced, external regulating schemes began to demonstrate their superiority over those using inherent generator patters. Out of the wealth of ideas advanced and tried, two distinct trends became evident.

1. The Diesel engine designer showed willingness to operate his engine at a fixed speed with fixed fuel injection and to accept whatever loading could be applied within these limits.

2. As a corollary to the first, the control designer became conscious that engine speed with fixed fuel injection is the best measure by which to adjust the generator demand.

It is with these elements in mind that the new excitation system for these locomotives has been designed.

The solid line curves in Figure 3 show the nominal generator output, with recognition of desired field current and armature current limits corresponding to the generator load demand which can be carried by a 2,000-horsepower engine operating at top speed.

No attempt is made to develop this as an inherent pattern, but instead the generator and exciter are arranged for an output shown by the top dotted curve, considerably in excess of all three limits. The setting is made high enough so that

all variations with temperature and with commercial tolerances between machines still will exceed the three limits.

Dependence then is placed on the power plant regulator to reduce the exciter excitation to the point where the generator demand will not stall the engine or to adjust it upward to the point where full fuel injection is obtained. In this manner the proper load limitation, shown by the solid hyperbolic curve in Figure 3, is obtained. The actual loading obtained will depend on the engine condition and other factors such as fuel and air temperature, but in any event the engine speed and fuel injection will be obtained at proper levels.

Further dependence is placed on the saturable reactor equipment to control the exciter excitation so that the desired limits of generator field and load current are not exceeded.

Exciter

An amplidyne exciter is used in the new excitation system. This is its first application in the railway locomotive field.

Full advantage is taken of the amplification factor in that all control devices are of small size and thus can be suitably located. For instance, the load control potentiometer is mounted directly on, and is operated by, the engine servo unit. Conventional capacitors are used for stabilizing purposes.

Excitation Circuits

The elementary connections are shown in Figure 4. The amplidyne exciter is connected to the generator shunt field through a contactor, with discharge resistor across it, and through one element of the saturable reactor equipment. This is for signaling excessive field current.

Figure 8. Typical connections and characteristic curve for tuned frequency relay equipment

Figure 9. Locomotive overspeed relay equipment

Antihunt field *F7-F8* is connected across the exciter armature through a stabilizing capacitor. During dynamic braking, an additional capacitor is added by contacts of the braking relay.

Suicide field *F3-F4* is used in conjunction with the exciter field relay to reduce quickly the generator field current to zero when the throttle is closed.

The control field *F1-F2* is energized from the locomotive battery through the load potentiometer on the power plant regulator and through resistor *152*.

To signal excessive generator current, the voltage drop across the generator commutating field is fed through resistors *116* and *116A* to an element of the saturable reactor equipment.

When the saturable reactor equipment receives a signal of excessive current either in the generator field or load circuit, a counter voltage is applied to resistor *152*, thereby reducing the *F1-F2* excitation to a value needed to observe the required limit.

During motoring, sequence relays *A*, *B*, *C*, or *D* operate to change the battery circuit bias on the saturable reactors to establish the desired generator load current limit for each throttle position.

During dynamic braking, an interlock on the braking switch cuts out resistor *116* to establish the lower current limit required. The braking relay connects the saturable reactor bias circuit to potentiometer *147*. This potentiometer is operated by the controller selector handle, and the voltage established on train wire 22 modifies the braking current limit simultaneously on all connected locomotive units.

The saturable reactor windings are insulated suitably so that the generator and battery circuits are not connected electrically.

The load potentiometer in the power plant regulator operates to control *F1-F2* field excitation so as to maintain whatever load the engine can carry at the specified speed.

When the traction motor demand is less than the engine can carry, the power plant regulator reduces the engine fuel to maintain the desired engine speed. Under this condition the load potentiometer is at the maximum voltage position.

As the motor load increases, more fuel is admitted to the engine up to the maximum value permitted. Load demands beyond this point produce an internal overtravel of the servo unit, which in turn operates the load potentiometer towards the reduced voltage position to lower the *F1-F2* excitation as required.

A feature of this system is the capacitor feedback from the generator shunt field amplidyne exciter circuit to the power plant regulator. Any large voltage

Figure 10. Axle generator for tuned frequency relay systems

change appearing in this circuit, such as occurs when the field contactor is opened momentarily during motor transitions from series parallel to parallel, signals the regulator in advance of the actual load change on the engine. Anticipatory regulator action thus is initiated, and any transient engine speed increase is prevented during the transitions. This feature is an improvement over older sys-

Figure 11. Water temperature relay

tems where the engine sometimes tripped out on overspeed during motor transitions.

Further details of the operation of both the saturable reactor equipment and of the power plant regulator will be found in other papers.

Dynamic Braking

With the development of a new air-cooled braking resistor of high capacity, dynamic braking is now available for the new locomotives of a rating limited only by the capacity of the traction motors themselves.

Power braking circuits are shown in Figure 5. An air-operated braking switch establishes the power braking circuits. This switch is interlocked suitably to insure its operation only when there is no power in the circuits. Each pair of motors is connected across half of the braking resistor. A blower motor with dual fans receives its energy from taps on one of the resistor halves. The blower speed is proportional to the energy being dissipated in the resistor.

The series fields of all four traction motors are connected across the generator through its starting field. This field acts differentially and allows the generator to be operated well up on its saturation characteristic, thereby providing maximum inherent stability.

Control of dynamic braking is obtained by operation of the selector handle on the master controller. This handle operates potentiometer *147* in Figure 4 to obtain any definite braking effort required. This voltage, appearing on the saturable reactor equipments on all connected cabs, establishes identical current limits on all the generators, and thus sets duplicate excitation levels on all traction motors.

The loadmeter, in front of the operator, is his guide as to the amount of dynamic braking. This meter, connected to a shunt in series with the Number 1 motor, indicates the actual braking current.

The amount of braking effort obtained at a fixed current depends on the locomotive speed as shown in Figure 6. A fixed selector handle position gives a braking characteristic as designated by the several curves for various percentages of field strength.

The system is stable. Any tendency for the locomotive to speed up is counteracted by increased braking effort, without movement of the selector handle. This is true up to the point where maximum motor armature current is reached and is indicated by a red band on the loadmeter. Further speed increase beyond this point must be met by a handle movement to reduce the dynamic braking, or by an application of the air brake, or by both.

Auxiliary Power Circuits

Although conventional battery charging circuits are used, new connections and equipment are involved in the air-cooling of the traction motors (see Figure 7).

The exciter, battery charging, and blower generator machines are gear driven from the end of the main generator. This eliminates difficulties and failures encountered with the V-belt drive formerly used. It also permits location of the blowers to best advantage.

A d-c system is used for the blowers because of its simplicity and for the important reason that its voltage level, and hence the blower speed and motor cooling can be raised during dynamic braking for a higher rating.

During motoring, the blower generator voltage varies with engine speed. During dynamic braking, with the engine at idling speed, an interlock on the braking switch commutates the blower generator field resistor so as to obtain approximately three-fourths of maximum air-cooling in the traction motors.

Tuned Frequency Equipment

The wartime development of tuned fre-

Figure 12 (left). Motor reverser

Figure 13 (below). Typical relay for amplidyne excitation system

Figure 14. Dust-tight equipment box

quency systems and of low energy relays have produced equipments suitable for handling a variety of tasks not attempted before on Diesel locomotives.

Prewar 2,000-horsepower passenger locomotives were equipped with voltage biased current relays for automatically transferring from series to parallel motor connections. These relays were not suited to handle backward transitions from parallel to series. It was the operator's responsibility to retard the throttle handle and to drop the relay back to the lower connection.

The 1,350-horsepower freight unit depended solely on manual operation of the selector handle for initiating the transitions. Results were satisfactory as long as the operator moved the handle at the correct locomotive speed. When he erred, the results in terms of shock on the train, and in the electric equipment, were most undesirable.

Figure 8 shows the connections and

Figure 15. Motor cutout switch

Figure 16. Circuit breakers

characteristics of a typical element of the new tuned frequency equipment. An axle driven permanent-magnet-rotor a-c generator supplies power with voltage and frequency proportional to speed.

A combination of reactors and capacitors, tuned to peak sharply at the desired speed and to maintain approximately the maximum output for frequencies above the peak value, operate a low energy relay through a rectifier. The sharpness of the curve is such that the pickup and dropout of the relay are within five per cent, in terms of locomotive speed. This means that transitions from series parallel to parallel can be set for 33 miles per hour and the reverse at 31.5 miles per hour. The low energy relay action is relayed to the locomotive control circuits.

By using similar equipments, each tuned to operate at the proper speed, completely automatic forward and backward transfers including field shunting can be had. On locomotives so equipped, the selector handle then is used as a restrictive lever to hold the connections at a lower level, if desired.

Similar equipments have been developed for locomotive overspeed protection. The circuit at the top of Figure 8 shows a double relay equipment *LS4* being arranged to operate a warning light at a speed just below that where *LOS* operates to cut off the engine power and to apply the air brakes.

Figure 9 shows a single stage locomotive overspeed relay equipment.

Figure 10 shows the axle generator developed to operate tuned frequency equipments. This is a permanent magnet 14-pole rotor with a 3-phase Y-connected stator, rated 50 volt-amperes for speeds from 15 to 120 miles per hour, with wheels from 36 to 42 inches in diameter. The unit is self-contained with its own shaft and bearings and mounts on the locomotive journal-box cover. The drive is by a double spline shaft, removable from the outside through the generator hollow shaft which enables the unit to be tested without moving the locomotive.

The application of tuned frequency equipments is not limited to that of motor transitions and locomotive overspeed. Similar equipments can be applied to modulate the locomotive and train air brakes for constant rate deceleration. The generator has sufficient capacity to operate a variety of these equipments, plus a speedmeter of the frequency responsive type.

Water Temperature Control

The new engines require a precise control of cooling water temperature. One

Figure 17. Typical circuit-breaker inverse time trip characteristic

Figure 18. Engine control panel

type of locomotive utilizes a radiator fan mechanically driven from the engine through an eddy current clutch. Modulation of the clutch excitation varies the degree of slip and affords a simple method of controlling water temperature.

Figure 11 shows a relay developed for this purpose. A vapor filled bulb and bellows system operates a set of contacts to advance or retard a motor driven rheostat for changing the clutch excitation. A suitable bias arrangement minimizes overtravel and undertravel, and means are provided for manual operation of the rheostat in the event of motor failure.

Traction Motor Reverser

A new butt-type silver-contact air-operated reverser was developed to obtain a small unit for handling four motors. It occupies the same space as formerly was required by the 2-motor drum-type reverser (See Figure 12).

Each layer is, in effect, a double-pole double-throw switch with a common contact and occupies a $3^1/_2$-inch vertical space. The contact pressure of 40 pounds is sufficient for the 1,000-ampere rating. An ingenious arrangement of the operating mechanism holds the unit in either of its two closed positions should the air pressure fail.

Control Relay

A new medium energy control relay was developed to match the rating of the amplidyne control circuits as shown in Figure 13.

This standard relay has four double-throw contacts, each with 10 amperes continuous rating and 0.5 ampere inductive interrupting capacity at 75 volts direct current. Space is provided in the base for one or more capacitors which, when connected across a contact, increases inductive interrupting capacity to 5.0 amperes at 75 volts direct current.

The operating coil rating is 7.5 watts. A variety of special forms were developed from the standard form including one with a latch to hold the armature in the energized position, another with less contacts for low energy operation.

Because of the type of contact used, these relays usually are mounted in a dust-tight enclosure.

Relay Box

Typical of the new practice of grouping related devices in a unit assembly is the relay box shown in Figure 14. This enclosure, with a glass inspection panel in the cover, houses all traction control re-

Figure 19. Engine control panel with doors opened

Figure 20. Laminated plastic indicators

lays with associated resistors, capacitors, and rectifiers.

All circuits enter the box through quick removable connectors. Replacement of the complete box involves only disconnecting the connectors and the removal of the four mounting bolts.

This arrangement facilitates a quick changeout of the complete box in the event of trouble and a more leisurely correction of the fault at a central servicing point.

Motor Cutout Switch

An interesting adoption of the wartime-developed small switch unit for low energy control circuits (see Figure 15) incorporates eight single-pole double-throw units in a cam operated device for cutting out the individual traction motors.

A multipoint connector connects all circuits to the unit and facilitates a quick disconnect in case of trouble.

Previous locomotives have used relatively large open-front knife-blade switches for this purpose, requiring an excessive amount of panel space.

Circuit Breakers

Until the present time, circuit protection on Diesel locomotives has been by fuses. Although these fuses have served their purpose well, there have been many cases of road delays and failures because of blown fuses which the crew could not locate or for which there was no replacement on board.

The arrival of the wartime-developed low-voltage circuit breaker has made it possible to eliminate completely all fuses on the new locomotives (see Figure 16).

These breakers are indicating, tripfree, and have sufficient shock resistance for locomotive service. They are available in ratings from 15 to 200 amperes, 75 volts direct current. The inverse trip time current characteristic of a typical unit is shown in Figure 17. Tests have shown an ability to interrupt the maximum short circuit to be expected on the locomotive battery circuits.

Most types use a thermal trip, and because of the effect of ambient temperatures care must be taken not to locate the units too close to any local heat; for example, the steam heat generator.

Engine Control Panel

A further example of co-ordinated grouping of related devices in a unit assembly is the engine control panel shown in Figures 18 and 19.

Included are gauges and switches formerly mounted in an unsightly manner on the side walls of the engine room. The new panel mounts all gauges, switches, and indicating devices needed for checking the engine operation, together with electric controls for the power plant regulator. The rotary switch on the front center is used for starting and stopping the engine. Intermediate positions are provided whereby the engine can be operated at partial speed and load, as when wearing in a new part.

A multipoint connector is used for all electric circuits into the panel and facilitates panel changeout in event of trouble.

Lighting

A number of lighting developments have been applied to the new locomotives.

Figure 21. Operator's view of control stand and of instruments on the dashboard

Figure 22 (below). Fixture for ultraviolet lamps

Figure 23. Section through cowl showing installation of fixture for ultraviolet lamps

Laminated plastics are used for control and position indicators (see Figure 20). This material has a black face on a white translucent back. Letters are engraved through the black layer and show as white in the daytime. They may be rear illuminated at night, as at the operator's position (see Figure 21).

Ultraviolet lighting (black lighting) has been applied to the electric instruments and air gauges on the dashboard in front of the operator. The wartime-developed *RP-12* fluorescent bulb was found satisfactory for the 75-volt d-c circuits when used with proper resistor control. A fixture (Figure 22) was arranged with suitable reflectors and filter glasses for mounting under the cowl (see Figure 23).

Instrument and gauge scales were finished in black with letters and figures engraved into the surface. Fluorescent paints in various colors were applied to the engraved markings and to the pointers. The ultraviolet illumination at night is not only pleasing to the operators, but is a real aid to the dark adaptation of the eyes to the low level illumination of the distant track, particularly at high speeds on a rainy night.

An experimental installation of fluorescent lighting of the engine rooms has been made on a few units. Standard 14-watt *T-12* bulbs are operated on direct current from the locomotive battery through a lamp regulator. A new fixture (Figure 24) was designed for mounting the lamp in rubber sockets. Mounts for the thermal starter and ballast lamp also are included. If no unusual troubles develop from the d-c operation, further applications may be made as the improved illumination and lower energy consumption are attractive features.

Apparatus Installation

Complete co-operation between the locomotive builders and the control engineers made possible a layout of apparatus superior to previous arrangements.

All traction control items are mounted in the contactor compartment. The compartment frame forms the rear wall of the operating cab. The design details were worked out in such a fashion that the assembly and wiring is done on the factory floor (see Figures 25 and 26). The finished assembly then is lowered into place in the cab, cables and wiring are connected. This method has produced a real saving in labor and time over previous methods.

The entire locomotive cable and wiring arrangement was designed according to the plans shown in Figure 27. Emphasis was placed on apparatus location that would give the shortest possible runs, consistant with location of devices entirely in three control centers. These are the control stand, the contactor compartment, and the engine control panel. The actual conduit locations follow closely the details shown on the plan.

New developments in solderless terminals were applied to all sizes of wire and cable (see Figure 28). These include swedge-on terminals for 750,000-circular-mil wire and indented terminals on number 16 wire. The labor saving inherent in this development is large and a better

Figure 25. Contactor compartment frame

Figure 24. Fixture for fluorescent lamp

quality job results. This is especially true of the large cables because the terminal application must be made after the piece has been pulled through its conduit. Often the cable ends are hard to reach and present real gymnastic problems to the workman with a solder pot. The portable press die presents no such problem.

Conclusions

The arrival of new and larger Diesel power units for locomotive service has required that new standards be created in precision of control of engine speed, engine loading, and in such associated matters as control of temperature of engine cooling water. Generator and motor improvements likewise have required more precise handling of the rotating electric equipment.

To meet these new requirements there have been many new developments. These consist of new excitation circuits, a new power plant regulator, an improved dynamic braking control, an automatic transition control, a new water temperature control, together with new apparatus and applications in the locomotive itself.

A Power Plant Regulating System for Diesel-Electric Locomotives

C. B. LEWIS
MEMBER AIEE

Synopsis: This paper describes a new power plant regulating system which incorporates speed and load control, recognizes the ability of the engine, permits maximum utilization of the engine's power, and protects the engine from harmful overloads. The ability of the regulator to schedule permissible engine fuel as a function of engine speed allows it to be used with the latest type engines employing supercharger. The system permits remote and multiple-unit operation and provides a high degree of plant protection against damage because of failures.

IN the adaptation of Diesel-electric power plants to locomotives, the problem of remote semiautomatic control is primordial. With few exceptions the present-day Diesel-electric locomotive consists of a number of power plants operating in multiple and under the control of a single operator who must be sufficiently free from mechanical chores to be able to devote maximum attention to the rail ahead and the speed of his train.

The control of locomotive speed is accomplished best by the control of locomotive power and this done by manual movement of a master controller handle which will modulate simultaneously the power of all units.

The individual power plants necessarily must be under the jurisdiction of some sort of regulator which will enable the unit to maintain a power level in correspondence with the setting of the master controller. The configuration of this regulating system is the chief concern of this paper.

Figure 1. Power plant volt-ampere characteristics

Summary of Regulator Functions

The regulator controls power plant output by

1. Controlling engine speed.
2. Controlling load by matching generator demand with engine ability.
3. Controlling engine torque as a function of engine speed (fuel limit).

The regulator also allows multiple unit operation and remote control. Finally, it protects the power plant by

1. Providing automatic shutdown against

(a). Overspeed.
(b). Low lubricating oil.
(c). Control failures.

2. Reducing power during unusual conditions as

(a). Overtemperature.
(b). During motor cutout.

Description of Regulator Functions

Speed Control

In the design of a regulator, the characteristics of the engine and electric transmission must be considered objectively. The characteristic of a Diesel engine at a constant speed is one of constant power or, in terms of the generator input, constant volt-amperes. The volt-ampere characteristics of a shunt generator with constant speed is shown in Figure 1 along with the engine characteristic. The power delivered by the power plant is controlled readily by controlling engine speed.

Load Control

In order to provide for full utilization of engine power over as wide a range of locomotive speed as possible, the generator characteristic must be altered to coincide with the engine characteristic over as wide a range in generator voltage as is possible. This can be accomplished between points B and C by a reduction in the generator field using engine speed as a reference. It should be pointed out that, if the generator characteristic is above that of the engine, the engine would be forced to run in a bogged condition or at a speed lower than that called for, which is harmful to the engine and results in decreased power. However, if the generator characteristic is lower than the engine characteristic, the full power ability of the engine would not be utilized. It is possible by means of the proper connection of the traction motors and their associated control to remain on the constant horsepower portion of the engine-generator curve (between B and C Figure 1) over an appreciable range in locomotive speed. The speed range which can be covered depends upon the gearing, the design of the electric machines, and the proper motor switching, and is beyond the scope of this paper.

Further consideration of the power plant characteristics, reveal that the output of a Diesel is not always the same at a given speed but is dependent on engine

Paper 47-39, recommended by the AIEE committee on land transportation for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted November 12, 1946; made available for printing December 6, 1946.

C. B. Lewis is with the transportation control engineering division of General Electric Company, Erie, Pa.

Figure 2. Tachometer-generator and over speed switch (typical engine mounting)

wear, ambient temperature, and calorific yield of the fuel. The generator characteristic is also variable and is influenced by the temperature of the copper in both generator and exciter. This is further evidence that the regulator should perform the function of load control which will match the generator and engine characteristics at all times while operating in the region of constant power.

Engine wear is a primary factor and it is desirable to run the engine at the lowest possible engine speed commensurate with the power requirements set by the master controller.

Fuel Limit

This brings into consideration another item which is particularly important with the use of the larger more powerful supercharged or mechanically aspirated engines of the type now being used in locomotives and that is the reduction in fuel necessary with reduced engine speeds. The air density of the cylinder charge and the amount of excess air for cooling valves and pistons decreases with speed as well as the amount of cooling water and oil. Therefore the permissible maximum fuel charge must be decreased in order to maintain safe mean-cycle temperatures. This makes it very desirable to schedule the engine fuel (torque) as a function of engine speed. The same considerations apply to a "bogged" or overloaded engine. Because the engine is running at a speed below that called for, the engine temperatures are certain to increase. A "bogged" engine not only means lowered performance but is one of the principal causes of engine failure. It is important, therefore, that the regulator does not allow the engine speed to fall off.

Multiple-Unit Operation and Remote Control

In multiple-unit operation each power plant must be operated up to the limit of its individual abilities and the division of load should be made on that basis. Inasmuch as all of the plants are operated remotely, the same operating signal from the master controller must be provided to all engines.

Automatic Shutdown

A very necessary consideration in a remotely controlled plant is automatic protection of important apparatus. Protection against overspeeding of the power plant, loss of lubrication, and loss of engine control should be provided as simply and reliably as possible and should shut down the power plant. As the electric drive is freewheeling, this can be done only at the expense of the complete loss of tractive power and the addition of the rolling resistance of the dead unit.

Reduction of Power Because of Unusual Conditions

Other conditions which may not warrant the complete shutdown of a unit but for which protection must be provided are high engine temperature and the loss of a traction motor. The modern Diesel-electric locomotive is equipped with automatic temperature control of a very reliable nature; however, should the engine temperature rise above the safe operating range, a reduction in the permissible torque (fuel) of the engine should be made without affecting the engine speed. By so doing, the heat rejection of the engine may be reduced sufficiently to return the temperature to a safe value and the unit left in operation. A cab warning also should be provided and if the high temperature persists the operator can shut down the unit before serious damage may be caused.

During operation with a traction motor

Figure 3. Power plant regulator (back view)

cutout, the remaining motors and the generator should be protected from overcurrents by reducing the engine torque (fuel) without affecting the speed. The reduction in power resulting should be sufficiently large so that the remaining motors operate at normal power.

Description of the Regulating System

The regulating system consists of the following devices:

Engine Driven Tachometer-Generator and Centrifugal Overspeed Switch

The tachometer-generator (see Figure 2) provides the speed signal to the regulator by producing a voltage proportional to speed. A 3-phase a-c machine with a permanent magnet rotor has been chosen because the output characteristics can be maintained uniformly among machines. Because the machine is engine mounted, the absence of brushes is an advantage. A visual indication of engine speed readily is provided at the engine panel by using a frequency-sensitive drag-type indicator driven by the tachometer-generator.

Figure 4. Engine control panel

The centrifugally operated switch is used to interrupt the holding coil on the regulator clutch and remove the engine fuel whenever the engine overspeeds. In case of an overspeed trip, the switch must be reset manually before the engine can be restarted.

Army-Navy connectors are used to facilitate the electrical connection and minimized "wiring errors" by maintenance personnel.

An Engine Mounted Regulator or Governor

This device (see Figure 3) incorporates

1. A speed responsive servo unit which controls engine fuel and generator excitation.

2. A positioning mechanism which serves as a fuel limit.

3. A magnetically latched spring restored clutch which overrides the speed servo unit and will remove the engine fuel whenever the holding coil current is interrupted.

4. A hydraulic pressure regulator which maintains the pressure on the hydraulic source for the speed servo unit and fuel limit. As this device is separate from the tachometer-generator, it can be located on the engine wherever it is most convenient to the fuel control system.

The use of an amplidyne exciter makes possible the control of generator excitation and load control by a small commutator type rheostat driven directly by the speed servo unit. This arrangement provides a very fast acting load control using little power and occupying a relatively small space.

The hydraulic supply to the regulator is provided readily by a d-c driven auxiliary motor pump set which has two pumps, one for use as a fuel transfer pump to supply fuel to the engine injection pumps and the other for pumping a good grade of light lubricating oil from a small reservoir to the regulator. This insures an ample supply of oil to provide proper regulation during transients regardless of engine speed.

The pump set is mounted off the engine and if desired also may incorporate a 400-cycle alternator for main generator current and field limits and furnish the ignition for the train heating boiler.

The electric connections to the regulator also are made in an Army-Navy connector for maximum convenience.

Engine Control Panel

This panel (see Figures 4 and 5) incorporates the necessary control components for the engine regulator, remote control, engine protection, and engine cranking. It is mounted on the locomotive cab wall as near to the regulator as possible to minimize the lengths of the connections, particularly those for pressure and temperature, so the operator may observe the action of the regulator during engine starting.

Figure 5. Engine control panel (covers removed and showing apparatus)

A plug connector is used for the connection of electric circuits. In detail the panel contains the following:

1. The engine control switch used for starting the engine, for controlling engine speed for testing purposes, and for switching the control to the master controller for actual locomotive operation.

2. The combined speed and fuel limit setting resistors and commutating relays. Four relays are used to commutate resistance in the regulator circuits to set the speed and the fuel limit in a manner to give eight steps of engine power. While it is possible to provide the regulator with the proper signal for either a step or a modulated control in a variety of ways, the relay scheme is the one that was first used on Diesel-electric locomotives and must be adhered to as standard if the newer locomotives are to be trained with the older ones without duplication in systems.

3. Tachometer-generator rectifier and safety relay. The a-c output of the tachometer-generator is rectified to provide a d-c signal to the solenoid operated pilot valve in the regulator. The safety relay de-energizes the clutch holding coil in case of circuit failure to shut down the engine.

4. Stabilizing capacitors for the speed control element of the regulator.

5. Indicating and signal devices for indica-

tion of power plant condition in the form of

(a). Engine speed indicator.

(b). Lubricating oil pressure gauge and low lubricating oil pressure switch with warning light.

(c). Pressure gauge for fuel oil header pressure.

(d). Engine temperature gauge and temperature limit switch with warning light and the relay necessary for fuel limit reduction.

(e). A boiler flame outlight also is included in the panel because of convenience of location.

(f). A signal relay to sound a warning gong in case of failure and an engine stop relay which provides shutdown of all units at once from a push button located on the master control stand.

Description of Operation

The operation of the system can be explained best by referring to Figure 6 which is a schematic sketch of the system.

Speed Control

The tachometer-generator produces a d-c signal in the solenoid which operates the pilot valve of the speed servo unit. The solenoid force is compared with the force of a reference spring and during balance conditions the pilot valve is lapped and the power piston is stationary. Because the force level for equilibrium is a constant, the speed circuit current is constant and the engine speed is determined by the circuit resistance and is proportional to it.

Load Control

A speed change will cause a corrective movement of the power piston and depending on the generator demand will regulate either the engine fuel or the generator field. Regulation of engine fuel will take place until the motion of the fuel control shaft is arrested by the fuel limit stop, after which the power piston can continue to move through the overtravel spring and reduce generator excitation by means of the load control potentiometer. The potentiometer is provided with blank sections so the generator has full field until the fuel limit is reached. When the plant is operating on the constant power characteristic, the engine speed is maintained by regulating on the generator field; the speed control servo unit is working in the overtravel region and the generator demand is made equal to the engine ability.

Because the power piston of the servo unit has no restoring force, the governor is isochronous and has no speed droop with load.

Inasmuch as the regulator is isochronous some stabilizing means is necessary, and this is accomplished by an antihunt winding in the control solenoid to which stabilizing signals are fed

1. As a rate of change of engine torque by the capacitor tie from the stabilizing potentiometer.

2. As a rate of change of speed by the capacitor tie from the tachometer-generator.

A blocking rectifier is provided to make the rate of response in the turn-on direction slower than in the turn-off direction.

A load anticipation signal is provided by the capacitor tie from the positive side of the exciter which is particularly helpful during motor switching in minimizing transient regulation.

Fuel Limit

The fuel limit mechanism, for mechanical expediency, consists of a power cylinder and solenoid valve, which is a duplicate of the ones in the speed servo unit. This system functions as a positioning system for the fuel stop which schedules engine torque as a function of speed. Inserting resistance in the speed circuit to increase the called for speed effectively removes resistance from the fuel limit circuit and the resultant increase in solenoid current causes the power piston to drive the fuel limit rheostat and insert resistance to rebalance the system. Schematically the stop is shown on the power piston of the fuel limit servo unit. In the actual regulator, however, the fuel stop takes the form of a cam, which together with a matching rheostat gives the desired torque schedule for the particular engine.

Multiple-Unit Operation and Remote Control

For multiple-unit operation, four train wires for the speed setting relays are required to each unit and the engine control switch *EC* must be switched to the run position.

If a new engine port must be run in at reduced speed and power, leaving the *EC* on position 6, this will cause the engine to follow the master controller up to the sixth notch but will hold the unit at sixth notch speed and power when the master controller is in the seventh and eighth positions.

Engine Protection

Interruption of the clutch holding coil circuit will remove the fuel from the engine by releasing an overriding spring and shut down the plant.

Figure 7 shows a view of the regulator with covers removed, showing the clutch, overtravel spring, and regulator interlock.

Power plant shutdown protection specifically provided for is

1. Engine overspeed (*EOT* contacts).
2. Low lubricating oil (*OPS* contacts).
3. Control failures.

(a). Loss of speed circuit (*SAR* contacts).
(b). Loss of regulator oil (*GOP* contacts).

Unusual Operating Conditions

During high temperature operation, the engine temperature relay *ETO* (actuated by a temperature bulb) commutates resistance in the maximum fuel limit trimmer circuit and reduces the fuel to a value corresponding to 75 per cent torque.

During motor cutout, the motor cutout switch *MCO* commutates resistance in the maximum fuel limit trimmer circuit and reduces the power to 75 per cent (for a 4-motor system).

The engine must be started by the operator from the engine control panel. After energizing the control circuit and starting the fuel transfer regulator oil pump set, the engine switch is turned to

Figure 8. General view of typical installation of regulator and tachometer-generator on engine

the idle position. This energizes the stabilizing coil and causes the power piston to close the clutch and the regulator "off" interlock and energize the clutch coil circuit. By pulling the *EC* switch handle away from the panel, the generator starting contactor energizes the auxiliary starting field and motors the generator. At the same time the stabilizing forcing circuit is removed and the power piston goes to the full "on" position. While the handle is in this position, the oil pressure switch *OPS* and the safety relay contact in the clutch circuit is by-passed by an *EC* switch contact and as the fuel turns on the regulator "off" interlock is opened (its sole purpose being to provide overlap in switching the coil circuit). After the engine fires and runs at idle speed, the oil pressure switch and the safety relay close, which permit the *EC* handle to be released, thereby disconnecting the generator from the battery and the engine left running at idle.

During cranking the engine starting contactor interlock *GS* short-circuits the minimum fuel limit trimmer so the engine can be started more quickly than would be possible on the normal fuel allowed for low speed operation.

To operate the power plant from the master controller, the *EC* switch is turned to "run" and the plant is ready for locomotive operation.

When it is desirable to test the engine, the speed can be controlled from the panel with five steps including idle and full speed being available.

Applications of the regulating system have been made to a number of power plants, both military and commercial, gas-electric and Diesel-electric, and operating experience indicates high reliability and improved performance.

Figure 8 shows application of the regulator and tachometer to a large new type Diesel engine for locomotive use.

The flexibility of arrangement possible because the regulator is separate from the speed measuring means will facilitate future application to a wide variety of power plants.

Discussion

T. H. Murphy (American Locomotive Company, Schenectady, N. Y.): The power plant regulating system outlined by Lewis' paper has been used in a considerable number of American Locomotive-General Electric Diesel locomotives. The equipment has been used on two sizes of engines, the larger being rated at 2,000 horsepower. The regulating and control system and rotating equipment had to be made as light and effective as possible, because the large engine was used in a single cab locomotive unit of 2,000-horsepower capacity with two 3-axle swivel trucks.

The regulating equipment outlined by the paper permitted minimum size generator as all special regulating fields were omitted from this unit. Also, the equipment does not include an inherently regulated exciter, but only the amplidyne exciter which is controlled through the regulator. Therefore, the rotating equipment is of minimum weight, assisting materially in the design of the complete locomotive to maintain a low weight per axle.

Previous control and governing systems have been completely separated with one set of equipment to provide proper generator regulation or loading and the other set to provide correct governing of the engine. The system in question combines both so that the governing of the engine and regulation of the generator is performed by what might be called the governing unit for the whole power plant. The governor functions without speed droop. Combined with the generator regulation to prevent engine overloading, are such added features as a current limiting device, a voltage limiting device, and an engine fuel limit, together with the so-called throttle and engine alarm systems integrated with the regulator.

The system is very quick acting and the control of power very uniform. This is difficult to explain by use of any circuits, diagrams or description other than to state that the system works to maintain a uniform tractive effort on the locomotive during acceleration once the operator has selected the desired operating point. The constant tractive effort related as it is to wheel slippage and other factors, tends to give very uniform performance of the locomotive and enables the operator, with a minimum of skill, to get the maximum at starting. This condition has been very noticeable on actual locomotives in service with maximum tonnage trains started without any difficulty on severe grades.

Extreme care has been used in applying the regulator to the engine to avoid installing it where it would be subjected to the greatest heat or to either lubricating or fuel oil. The locations of both the tachometer-generator and governor are shown clearly by the photographs. The structure of the units has been made so that the insulation is particularly impervious to the action of heat and oil such as might be obtained on an engine application. The current limit feature has given added safety against false operation such as with locked brakes and, of course, it is set above the wheel slippage point of the locomotive. This feature is inherently related to the constant tractive effort or constant accelerating current feature which gives the uniform accelerating characteristics to the locomotive.

The earliest schemes of regulating devices were with straight generator field control, and later developments include control systems of the differential regulation type. These two schemes had independent engine governors. Following the generator field and differential control schemes, came the so-called speed controls. This power plant regulating system is based inherently on speed regulation which seems established through the locomotive industry as the best established means for this purpose.

T. R. Rhea (General Electric Company, Schenectady, N. Y.): I am not familiar with locomotive power plants, but these regulators or electro-hydraulic governors have been applied to Diesel-electric oil-well-drilling rigs.[1] Perhaps a discussion of the operation of this Diesel-electric drilling rig with its governing system will assist in emphasizing some of the points made in Lewis' paper.

This drilling rig consists of three 700-horsepower Diesel engines, each driving a 400-kw d-c generator and each provided with the electro-hydraulic governor described by Lewis. These engines are run over a speed range of 450–900 rpm, depending upon the desired output. For hoisting, all three generators are paralleled and supply a 1,000-horsepower motor; while for drilling, they are separated and supply individual mud pumps and rotary table motors.

Since the driller does not have time in his normal operations to attend to the paralleling of the engines, the governor attends to this function automatically and insures that all of the engines carry the proper shares of the load.

The second great advantage is the load-limit feature of the governor that prevents the engines from being overloaded no matter how heavy a pull or lift the driller is trying to make on the engines. The third advantage of this governing system on the drilling rig is that it permits the engines to run at half speed a great part of the time.

The governor or regulator on the drilling rig described does not have such features as engine overspeed and engine temperature since these are taken care of by other devices and are not considered necessary.

The governors have been in successful operation on the drilling rig now for a number of months and it is expected that they will show considerable advantage in engine maintenance and fuel savings over previously used unregulated systems.

Modern Car Equipment for New York City's Subway System

B. F. CORDTS
NONMEMBER AIEE

TO meet the increasing need for additional car equipment, the Board of Transportation has placed orders for 400 subway cars to be operated on the BMT and IND divisions, and for 100 subway cars to be operated on the IRT division of the New York City Transit System.

These cars when put into operation should provide the traveling public with

1. Better lighting.
2. Better riding qualities.
3. Smoother acceleration and deceleration.
4. Reduction in noise.
5. Other items for passenger comfort.

Each of the five items will be discussed in detail after a few remarks about the cars in general.

The arrangement of the floor plan of the new cars remains essentially the same, that is, the 60-foot car for the BMT and IND divisions will have a floor plan similar to the present IND cars. This floor plan was selected by a committee of experts after an exhaustive study back in 1927. The investigation involved passenger movements through various sized openings, door spacing at the platforms, and the arrangement of seats in the car.

Comparative estimates were made for line capacity and operating efficiency for most of the 75 or more different arrangements considered. Their sound judgment in the selection made has been justified amply by actual performance in service over the past 14 years. The dimensions and arrangement of the new IRT car also follow the latest type built in 1939. These cannot be changed in width, height, or length because of limitations of the present subway structure.

Wherever possible the body structure and equipment of both types of cars have been made standard to take advantage of the full benefits of such standardization. An artist's sketch of the exterior of this car is shown in Figure 1.

Lighting

The need for better car lighting has been recognized by car designers and, as more efficient lamps were developed, higher light intensities became possible without increasing the number of lamps. The improvement from the 5 circuits of 36-watt 5-in-series lighting to the 22-in-series 1.6-ampere lamps was a long step in the right direction. Based on their respective nominal ratings, the lumen output was increased from 9,125 to 15,455. This represented an increase of 69 per cent for approximately the same wattage.

With the introduction of fluorescent lamps, a new source of light, ideally adaptable to car lighting, presented itself. Tubes of fluorescent light placed end to end for the length of the car provided a distribution of light impossible to obtain by any other means.

The problem then became one of selecting the type best suited to the specific requirements of subway service. The two types of fluorescent lamps are classified as hot cathode and cold cathode, each having several desirable and undesirable characteristics. Without going into the details of the investigation and tests conducted to determine which type would be better, the cold cathode lamp was selected for the following reasons:

1. Long life.
2. Life independent of frequency of starting.
3. Instant starting.

These characteristics are most important in subway operation, particularly items 2 and 3, as the number of third rail gaps caused by section breaks and crossovers is very high. For example, on the IND division between 207th Street, Manhattan, and Rockaway Avenue, Brooklyn, 27 interruptions were recorded. This is a run of 19 miles. Based on 60,000 miles per year and the same rate of interruptions, the lamp would be started 85,000 times. This is far above the number of starts any of the present hot cathode lamps could withstand.

The new car will have 24 72-inch cold cathode lamps operating on 600 volts direct current. These lamps have a lumen output of 1,600 when operating at 110 milliamperes and with their ballasts

Figure 1. An artist's idea of the general perspective of the new car

Paper 47-43, recommended by the AIEE committee on land transportation for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted November 13, 1946; made available for printing December 13, 1946.

B. F. CORDTS is with the New York City Transit System, New York, N. Y.

have an over-all wattage of 66. Compared to the old IND car using 22 1.6-ampere lamps in series, an increase of 148 per cent in lumen output is obtained for an increase of 65 per cent in power consumption.

Resistances were used in the circuit in place of two small ballast lamps as we felt that the variation in light output, shown on curves in Figure 2, caused by voltage variation was not sufficient to warrant the added maintenance that would be entailed by the use of the small ballast lamps and sockets. Voltage fluctuations are of relatively short duration, although the swing may be large, ranging from 400 to as high as 750 volts.

The circuit for the cold cathode lamp on 600 volts is shown in Figure 3.

Riding Qualities

The subject of riding qualities always has been a problem to the designer. For many years good or bad riding qualities were a matter of personal opinion, and there was no instrumentation available for measuring these factors. This was the first difficulty Professor C. F. Hirshfeld encountered when he undertook the work for the Presidents' Conference Committee which led to the now well-known PCC trolley car. By placing various types of people, young, old, thin, fat, and so forth, on a vibrating table controlled insofar as amplitude, frequency, and direction of movement are concerned, he was able to establish what he termed an "average comfort zone." This zone was determined by curves of amplitudes and frequencies in vertical, horizontal, and longitudinal directions. Instruments were developed to measure and record the various factors.

Many tests were conducted on subway cars and the records analyzed to see what the effects of various changes made in the truck had upon the riding qualities of our own cars. From these tests certain factors were found to be desirable and were incorporated in the new design.

Without going into the details of each item, the following changes from present construction were made:

	New Cars	Old Cars
Truck frame	Cast steel	Built-up
Bar	Equilizer	Arch
Springs	Coil	Elliptic
Center plate	Conical	Flat
Shock absorbers	Vertical and lateral	None
Bearings	Roller	Plain
Insulation	Rubber*	Rubber

* Increased over old cars.

Add them all together and they "spell" better riding.

Acceleration and Deceleration

Considerable thought and study were given to the question of acceleration and deceleration—first to determine the desirable rates and then to methods of obtaining and controlling them. Rates of 2.5 miles per hour per second acceleration and 3 miles per hour per second deceleration were selected.

The extreme rate used for the PCC car, principally on account of the desirability of maintaining its position in street traffic, was not deemed necessary for subway operation for the following reasons:

1. *Increased Power Required.* Power peaks would be increased materially if higher acceleration rates were used. This high demand on power generating stations during morning and evening rush hours would affect their operation, and in the case of purchased power would raise the total rate. The power rate is computed monthly from two factors—the maximum kilowatt demand for one hour and the total energy furnished in kilowatt-hours. Roughly, the proportion of each factor is 50 per cent of the total.

2. *Complete Change of Type of Control.* Rheostatic control with a large number of steps would be necessary for the higher rates of acceleration to provide the small current increments required to keep it smooth, and also to avoid the difficulties encountered in transition from series to parallel at the high rates. A saving of approximately four to five per cent in power can be made by using series-parallel control. In addition, a switching notch for short movements of cars, such as are necessary for coupling cars, is provided, and a slow speed running notch at the full series position is also available. Facilities in the shops for maintaining unit switch type control and the familiarity of maintainers with this type of control also were considered in making our decision.

3. *Comfort of Passengers.* The comfort of passengers, of course, is of prime importance in the sale of transportation. With large numbers of standing passengers, and with others on longitudinal seats and on seats facing in the opposite direction of travel, we felt that accelerating rates in excess of 2.5 miles per hour per second were too high.

4. *Relatively Small Increase Obtained.* Analysis of typical speed time curves indicated that in changing the acceleration rate from 2 miles per hour per second to 2.5, the average increase in schedule speed is 1.3 per cent. From 2.5 to 3, the increase is less than 1 per cent. Applying this figure to average schedule speeds of say 20 miles per hour for local service, the result is 20.2 miles per hour, or a saving of 36 seconds in one hour of running. This certainly is not worth the added cost and possible discomfort to passengers. From three miles per hour per second up, the law of diminishing returns goes to work with increasingly poor results, insofar as scheduled speeds are concerned.

Deceleration received the same consideration and a dynamic rate of three miles per hour per second for seated load conditions was selected for the following reasons:

1. *Increased Size of Motors Required.* Since the required capacity of the motors is determined by the combined accelerating and dynamic braking duty, higher braking rates would necessitate larger motors, involving additional costs and weights.

2. *Change of Control.* Dynamic braking was not carried to zero resistance on the new

Figure 2. Comparison of light output with variation of line voltage using different types of ballast

A—Incandescent lamp ballast

B—Fixed resistor ballast

C—Typical incandescent lamp

equipment on account of the large number of steps required in the lower speed ranges. It starts to fade at about ten miles per hour at which time air is applied and used to the final stop. Combining the dynamic and air at this point permits time enough so that the blending is perfectly smooth. The amount of work left for the air brake is a very small percentage of the total. Assuming a stop were made from 40 miles per hour and that air did all the work below ten miles per hour, only a little over six per cent of the kinetic energy would be dissipated by the brake shoes.

3. *Comfort of Passengers.* The same comments apply here as in the case of acceleration. A maximum rate of three miles per hour per second is maintained on account of the signal control and, where full load conditions reduce the dynamic rate, sufficient air is used to supplement the dynamic braking so that the rate of the operator is calling for is maintained.

4. *Relatively Small Increase in Schedule Speeds.* Here also the law of diminishing returns applies. Because of the short interval involved in braking, any increase above the three miles per hour per second rate would be even less effective than a corresponding increase in acceleration.

Figure 3. Circuit diagram of cold cathode lamp with fixed resistor ballast

Reduction of Noise

Certainly the desirability of noise reduction in subway operation is not controversial, though some of the previous items may be. It is a difficult job to do effectively on account of the enclosed structure which permits sound waves to reverberate with very little absorption, but every effort was made to obtain the best results possible. Without developing new features, the specific details of our efforts toward noise reduction in these cars are as follows:

1. *Use of Rubber.* Rubber is used at important points of contact such as between the equalizer and the journal box, the truck frame and the equalizer spring, the bolster and the bolster spring, and the bolster and bolster guides. This should insulate the car body from the high frequency vibrations effectively and materially reduce impact forces.

2. *Motors and Gears.* Motors are truck mounted, being hung on the transom and connected to a separate gear unit through a flexible coupling. This reduces the unsprung weight and prevents the transmission of road shocks from the wheels and axle to the motors.

High angle helical gears running in oil were selected for quietness and low tooth loading. They are single reduction for simplicity and low cost. Motors and gear units are equipped with antifriction bearings throughout, so that accurate clearances can be maintained. This is very important on account of the high rotor speeds and small air gaps.

3. *Lateral Shock Absorbers.* The older subway cars had a tendency to nose, causing lateral motion of the car body when certain factors reached a resonant stage. A long series of tests lasting over several years developed information which led to changes in basic truck design and to the adoption of a lateral shock absorber between the truck bolster and the side frame. On tests conducted with this application the striking of the bolster against the side frame was eliminated.

4. *Center Plates.* Conical center plates on bronze bearings and in an oil bath will reduce the slap between the body and the truck center plates. This construction also will reduce the force required to turn trucks on curves, resulting in lower flange pressures of the wheel against the rail, thereby reducing squealing and increasing the life of both the wheel flanges and rail heads.

5. *Dynamic Braking.* The use of dynamic braking will reduce the number of shoe applications to the wheels, and also the shoe pressures. As explained under deceleration, only about six per cent of the total work required to be done in stopping the train will be done by the brake shoes, thus eliminating most of the frictional noises between shoes and wheels.

6. *Brake Cylinders Mounted on Trucks.* Brake cylinders have been mounted on the trucks, thus avoiding the use of foundation brake rigging on the body.

The noise level of operation within the subway structure with present equipment averages 89 decibels. The elimination or reduction in magnitude of the foregoing factors will have a noticeable effect in lowering the noise level.

Other Features of the New Cars

In the first part of this paper the four major changes in the newest cars were discussed in detail. This section will cover a summary of the smaller items which will add to the comfort of passengers.

Four motors per car, one per axle, were selected so that accelerating and braking loads would be distributed evenly and kept within the normal adhesion factor of wheels and rail.

Thermostatic control of heat will provide more uniform temperatures and utilize the body heat of passengers during crowded periods. Tests indicate that heaters are "off" 75 per cent of the rush hour period. This will reduce power costs through the reduction of the "maximum demand" peak.

Eight 10-inch horizontal fans will provide a much better distribution of air than the five fans blowing vertically in the old cars. With fans blowing vertically about 30 per cent of the car area is in a high velocity downward air stream and the balance of the car has very little air movement. The horizontal fans will move air over every passenger location, seated or standing.

An effort was made to improve the cleanliness of both the car and the subway proper. The car interior is designed for easy cleaning. All surfaces were kept as smooth as possible, and corners were coved and rounded. Exhaust ventilation will improve cleanliness of the ceiling. Dynamic braking will reduce the amount of iron dust from brake shoes and wheels. Completely sealed gear cases will eliminate the grease drip which is so objectionable.

Plastic seat coverings, impervious to all common acids and alkalies, will be used in the upholstery of the cushions and backs. It is colorful, easily cleaned, and well able to take the daily wear and tear without becoming shabby.

Additional space for passengers was obtained by changes in car body construction. Narrower side posts and recessing interior finish under window sills provided wider aisles as well as longer seat cushions. Wider door openings will facilitate the interchange of passengers.

The color scheme for the interior has not been decided definitely, but it is anticipated that the scheme selected will be pleasing to the passengers.

Discussion

G. M. Woods (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The use of four high-speed spring-borne motors, instead of two axle-hung motors, on the New York, N. Y., subway cars is of great interest to electrical engineers engaged in transportation work. The conditions of operation are extremely severe and the effects of any apparatus failure in this service are so far-reaching that the greatest care in the selection of equipment must be exercised.

The application of high-speed motors was initiated on light-weight surface cars some 20 years ago. Today, all modern street cars have high-speed spring-borne motors. The 25 multisection cars of the New York city transit system employ high-speed motors with gear unit drives. These cars represent the only commercial application of this type of equipment to rapid transit service. On the new cars for the BMT and IND divisions, the load per axle will be 25 per cent greater than on the multisection cars and the motors will have one-third more capacity.

The application of motors to all axles gives traction on all wheels. This makes dynamic breaking and the higher rates of acceleration discussed by Cordts practicable. The motors are desigued for 300 volts and are connected two in series for 600 volt operation. The 300-volt motor compared to the 600-volt motor is more stable, has better commutating characteristics, and its commutator and windings are mechanically stronger. Peak voltages in dynamic braking are much lower.

The motor has a 1-hour rating of 100 horsepower and 300 volts at 1,175 rpm. The motor alone weighs 1,770 pounds and the gear unit with suspension bolt and coupling weighs 1,010 pounds. The maximum safe speed with worn wheels is 55 miles per hour.

Single reduction gear units are used. The gear case is of cast steel and the gears and tapered roller bearings are oil lubricated. The gears have a 4-inch face, 5.25 diametral pitch and 21-degree helix angle.

The couplings are of the internal-external gear type. The internal teeth are in a pair of cylindrical sleeves bolted together through flanges at their inner ends. The external teeth are on a pair of pinions, one on the motor shaft and one on the pinion shaft of the gear unit. The external teeth are so shaped that the pinions can swivel freely with respect to the internal teeth throughout the required angle.

L. G. Riley (Westinghouse Electric Corporation, East Pittsburgh, Pa.): From the standpoint of the motor control equipment, the discussions in this paper covering the characteristics of acceleration and deceleration are very interesting.

Riding comfort is influenced by the rates of change of speed, and also by the total number of notches or steps in the controlling system. In going to a 2.5 miles per hour per second starting rate, as compared to the 1.75 rate used on the present IND system, the number of notches will be more than doubled. This is probably more than would be required for the increase in rate alone, but is justified to obtain increased riding comfort and to limit the power peaks.

Dynamic braking will be controlled by the same switching apparatus as is used for acceleration and with the equivalent number of notches.

In developing the detail characteristics for new cars, the board of transportation engineers have very properly taken into account the shop and operating problems involved in adding new equipment to the existing system.

One of these features is the use of practically identical arrangements for the operating cabs, including the location and functioning of the power and brake levers.

This makes it necessary to combine the control of the dynamic and air brake systems on a single brake lever in a manner to insure that each will automatically do its allotted share of the braking duty.

During the initial application and build-up, air will be locked out of the brake cylinders by dynamic load current, except for the small amount required to maintain the full rate on cars having more than the average seated passenger load.

The lock-out feature will be nullified when the speed drops below 10 miles per hour and brake cylinder air will be admitted to make up for the gradual loss of dynamic retardation and to complete the stop. Full use of the self-lapping air brake system will thus be made available for graduation and for spotting the train at the station markers.

Control of power application, with running positions for switching, series and parallel, will also be identical, so that there will be only minor changes in the training of operators.

Special 10-Car Train for the New York City Transit System

J. J. SINCLAIR
NONMEMBER AIEE

IN AN EFFORT to obtain for the subways of New York, N. Y., a most modern type of car, the Board of Transportation has designed a car for use in an experimental 10-car train, embodying many special features not heretofore used in one application in a transit vehicle. Figures 1*A* and 1*B* show artist's rendering of side elevation and interior, and Figure 2 shows plan, side, and end elevation of this proposed subway car.

It is proposed to make their performance and appearance as attractive as possible to the traveling public.

The motor control has been designed so as to give smooth acceleration of $2^1/_2$ miles per hour per second; higher rates would not seem desirable for rapid transit service where comparatively infrequent stops are concerned.

Dynamic braking has been provided, supplemented by air brakes. All axles are driving axles which permit an even distribution of tractive effort and the elimination of wheel slippage.

The motors are of 100-horsepower capacity, full spring supported and capable of producing a maximum dynamic rate of 3 miles per hour per second with a full seated load and interlocked to provide a maximum available dynamic brake with a minimum amount of air required.

The dynamic brake interlock with electropneumatic and pneumatic brakes provides sufficient air brake to produce a retardation rate of 3 miles per hour per second on a fully loaded car for maximum normal service rate.

An automatic emergency pneumatic and electropneumatic brake is available at any time through the emergency position of the brake valve handle, the deadman controller, conductor's valve, track trip or parting of the brake pipe or brake pipe hose.

There are many features included in the design of the car body and trucks which are of special interest where the complete performance of the car is involved, and these are as follows:

Body Construction

Body construction is of aluminum high-tensile low-alloy steel, or stainless steel, or combinations thereof, to obtain a light weight body of strength comparable with the present IND division subway cars.

General Dimensions

The general dimensions of these cars will remain the same as those on the IND division, which are governed by tunnel and subway construction clearances. The roofs will be of turtleback design and, as far as practical, have a streamline appear-

Figure 1*A* (above). Artist's rendering of side elevation of proposed new special car

Figure 1*B* (below). Artist's rendering of interior of proposed new special car

Paper 47-44, recommended by the AIEE committee on land transportation for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 13, 1946; made available for printing December 13, 1946.

J. J. SINCLAIR is with the New York City Transit System.

Figure 2. Plan, side, and end elevation of proposed new special car

ance. Anodized aluminum or stainless steel mouldings on the exterior of the cars add to the general exterior appearance.

The general floor plan remains practically the same as in present cars. Past experience leads us to believe the present arrangement of seating is the most practical for quick loading and unloading of cars in New York subway service.

Such a floor plan, in combination with the doorways which have been increased from 46 inches to 50 inches, provides for a uniform distribution of passengers.

Changes in seat frame construction were found desirable to provide for the installation of outlets required in combination with the ducts for forced ventilation.

Seat upholstering is of the most modern material and color selected to obtain a most pleasing effect in combination with the general scheme of interior decoration.

Three wide windows on each side of the car, each having an upper half as a drop sash and the lower half stationary, will give standing passengers, as well as seated passengers, a better view of stations along the route. Two circular windows in each door add to the general appearance of the car.

The flooring is of magnesite on truss plate construction. Parting strips and special treatment of color in combination with the interior color scheme of the car has been given considerable thought in order to obtain a most pleasing effect.

Forced Ventilation and Heating

Forced ventilation is one of the outstanding features of these cars. By the use of blowers concealed in the ceiling at each end of the car, air is taken from the car interior through a large grill, passed over four 36-inch 25-watt sterilizing lamps and then into a plenum chamber between the ceiling and the roof sheets, thence out into the car as recirculated air, distributed uniformly throughout the length of the car by means of specially designed distributors. The blower motors are of 300-volt type, connected two in series on the 600-volt d-c line. When operated at 1,750 rpm on full field, each will deliver 2,660 cubic feet per minute. Provision has been made, however, for tapping the fields of these motors by the use of a contactor under thermostatic control. This provision contemplates the requirement of more air delivery by the blowers on excessively hot days and crowded car conditions. It is believed that by setting the thermostats at 85 degrees Fahrenheit, the motor fields will be tapped and the air delivery of each blower will be increased from 2,660 cubic feet per minute to 3,320 cubic feet per minute, and the speed from 1,750 to 2,200 rpm with 600 direct volts on the line. The fields are tapped automatically by the thermostatic control, governed by temperature in the respective cars.

It will be noted that the capacity of this recirculated air system with blower motors in full field is calculated at 5,320 cubic feet per minute total per car, which is increased to 6,640 cubic feet per minute on tapped field. Since a certain amount of fresh air will enter the car at station stops and through windows when open, a large proportion of this recirculated air will be fresh air.

In addition to the air movement obtained by this recirculating system, fresh air is drawn into a plenum chamber near the roof at each end of the car by two 1,500-cubic-feet-per-minute blowers mounted on the car underframe. This fresh air intake which is controlled by a system of dampers and thermostats, is passed through precleaning tubes which take out dust particles down to 10 microns; then over Precipitron units where fine particles are ionized and deposited on plates of opposite polarity, and finally over sterilizing lamps before entering ducts for distribution to air distributors mounted underneath the longitudinal seats of the car.

There are a total of 14 such outlets, and back of them in the air ducts are located strip heaters for heating this air during the heating season. This heating system is under thermostatic control and the total output is 18.2 kw per car with the heater elements connected in four circuits of seven elements in series on each circuit.

The outlets for this fresh air system have been designed so as to direct the air toward the floor fanned out to 180 degrees to be effective in producing a warm floor in the heating season and supply heated air at low velocity to the maximum number of passengers. The calculated velocity of this air on leaving the distributor will be not more than 210 feet per minute. Actual tests in a mockup car section indicate that this air velocity will not be disturbing to passengers, and will be comforting at their feet level in inclement weather.

The fresh air system will add a maxi-

Figure 3. Schematic diagram of ventilation, air filtering, and sterilization in proposed new special car

mum of 3,000 cubic feet per minute of fresh filtered and sterilized air to the car, making a total of 9,600 cubic feet per minute maximum of recirculated and fresh air turbulence within the car. See schematic diagram shown in Figure 3.

Lighting

Cars are illuminated by means of fluorescent lighting. Two rows of fixtures extend for the full length of car on either side of the centerline of the ceiling, and two crosswise fixtures are placed one at each end, providing 17-foot candles on the reading plane throughout the car.

Each row of lighting fixtures in the ceiling contain eight 72-inch hot-cathode tubes of 38-watt rating at 118 volts alternating current, two lamps per ballast with instant starting. Two 42-inch lamps are mounted cross-wise at the ends of the car, each with a rating of 25 watts, 118 volts, alternating current, with a starter for each lamp. These lamps are so distributed in each phase of a 3-phase, 118 volt circuit as to reduce to a minimum any stroboscopic effect.

Station Announcing System

A station announcing system is provided, having reproducers mounted in the ventilating air distributors along the centerline of the ceiling, with one microphone mounted on each end of the car at corner posts at the cab side on the outside, which is a convenient location for trainmen in announcing station stops before doors are opened and after they have closed. All microphones in the train will be dead except the operating microphones at the time of announcement. This is accomplished by a foot switch mounted in the trainman's step, and an interlock in the door control drum switch.

Only one train-line wire is used throughout the train, connected to an amplifier in each car. These amplifiers operate from the 32-volt car battery. There is a semi-fixed volume control provided in the amplifiers to be adjusted to suit the service.

Electric Door Operators

Electric door operators are included instead of air-operated equipment originally considered for these cars. They operate the doors at the same over-all speed for both opening and closing as the air operators. The motors are wound with Class B insulation, and will not be damaged by interruption of door movement throughout the door operating cycle.

Motor Alternators

All power for fluorescent lighting, including exterior car lighting, side sign lights, illuminated maps, sterilizing lamps, Precipitrons, and car battery charging, is obtained from a motor alternator. The motor alternator has a full load rating of 4.2 kva at 90 per cent power factor, and 118 volts, 60 cycles, 3 phase. The 32-volt car battery obtains its charge through a 3-phase full wave rectifier using selenium rectifier units and having a two-step charging rate. A regulator automatically chooses the charging rate depending on the condition of the battery. The motor alternator maintains an alternating voltage at 60 cycles plus or minus 2 cycles under all conditions of load with a d-c supply voltage of 450 to 650 volts maximum. With unusual supply voltage swings of 400 to 750 volts direct current, the frequency is maintained at 60 cycles plus or minus 4 cycles. In order to maintain the frequency and voltage, expecially for interior lighting in passing over gaps in the third rail with a maximum interruption in d-c supply of 10 seconds, a flywheel is included on the shaft of this motor alternator.

Trucks

Two types of light weight trucks of special design are being considered for these cars. (See Figures 4 and 5). They embody new features for rapid transit service, such as the elimination of the full elliptic bolster springs, spring planks, and swing links. The bolsters are supported at each end by helical springs with lateral and vertical movement controlled by lateral and vertical shock absorbers as well as by rubber pads between the transom and bolster.

Hypoid gearing with right angle drive through flexible shafts, and couplings will apply power to each of the car axles from the 100-horsepower motors mounted on the truck frames.

All journal bearings are of the roller type. All wheels are 34 inches in diameter, and are of the resilient type, designed for a maximum wheel load of 14,500 pounds.

It is believed that with the generous amount of rubber included in these trucks in combination with resilient wheels and flexible drive, stresses in truck frames will be minimized, nosing reduced, and much quieter performance obtained.

With completely sealed gear cases and roller bearings, oil or grease drip to the trainways will be eliminated.

Noise reduction is one of the outstanding features of these trucks. With the elimination of practically all brake rigging and simplified truck construction, comparatively quiet performance is expected.

All axles are driving axles, and each

Figures 4 (above) and 5. Two types of lightweight trucks proposed for special car

axle will be equipped with an air-operated drum brake which supplements the dynamic brake obtained from the driving motors. Provisions have been made for obtaining full braking rates in the event of failure of the dynamic braking, which normally will do all the braking down to a speed of 10 miles per hour when the drum brake will engage to make the stop. Under heavily loaded conditions the drum brakes in combination with the dynamic brake will maintain the three miles per hour per second braking rate as a maximum service rate. Any degree of service braking below the maximum rate is available as determined by the brake valve handle position in the normal service quadrant zone.

Discussion

G. M. Woods (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The motors of the cars described by Sinclair will be similar to those of the cars covered by Cordts except they will be mounted at right angles to the axles and will drive through hypoid gears. The accelerating and braking rates will be the same on all cars but the balancing speed of the experimental cars will be slightly higher than the others because of the lower weight. The rates of acceleration and braking selected are believed to be as high as practicable for the conditions of operation.

An Improved Automatic Circuit Recloser

J. M. WALLACE
ASSOCIATE AIEE

Synopsis: Several years of field experience with automatic circuit reclosers indicated room for worth-while improvements in the existing design. This earlier recloser incorporated time-lag tripping characteristics to allow co-ordination with other reclosers and with fuse links. The improved design helps reduce outage time by extending the range of co-ordination with fuses by means of high speed tripping and reclosing. This paper describes the new recloser and points out the application of its new features.

Recloser Operating Characteristics

Early Recloser

IN 1941 an automatic recloser with inverse-time-lag tripping was described to the Institute.[1] This paper proposed several methods of using the recloser described to sectionalize radial distribution systems. One method was the extension of the reclosing function to the fuse cutouts which are located on the load side of the recloser. To obtain this operation, the fuse link and recloser combination is selected so that for a fault on the load side of the fuse the recloser will interrupt the circuit before the fuse link is damaged. If the fault is temporary, the line is re-energized on reclosure without a needless fuse operation. If the fault is permanent, the fuse is blown on the second or third successive reclosure because of the heat stored in the fuse link by the fault current on the previous operations. The fuse cutout then isolates the fault in the conventional manner, and the recloser can re-energize the rest of the distribution system which it controls.

The recloser described at that time has been in successful operation for more than six years. Co-ordination of reclosers with each other is foolproof provided they are located in descending order of ampere rating proceeding away from the power source. However, the co-ordination of reclosers with fuses in the manner described is sometimes difficult to achieve over a sufficiently wide range of fault currents.

Improved Characteristics Needed

To improve co-ordination of reclosers and fuse links, the tripping characteristics of the recloser should be changed from all time-lag to high-speed (instantaneous) tripping on the first and second operations followed by time-lag tripping operations until lockout. In this fashion, fuses may be protected by the recloser over a wider range of fault currents. However, the reclosers forming the main line of the distribution system should utilize time-lag tripping on all operations. These are the reclosers located at the first two or three points proceeding outwardly from the power source. In this fashion, the backbone of the distribution system is kept stiff and the entire system will not suffer power interruptions from troubles which should be confined to the branches. Smaller sizes of reclosers protecting branches can use the high speed tripping as power interruptions, thereby, are confined to the branches and are not communicated to the entire system.

The co-ordination of fuse links and reclosers must be planned adequately by the use of proper time–current curves. Because of the fast-blowing characteristics of small fuse links, it is impossible to protect them with the larger sizes of reclosers as fault currents on branches near the power source are likely to blow the fuse link in the first half cycle. Thus, even though the substation recloser is set for instantaneous tripping, it cannot protect the small branch fuse and the only result is to cause many needless interruptions affecting the entire systems.

Characteristics Required of Instantaneous Recloser

A study of the literature applying to the reclosing of transmission and distribution lines after faults shows the following cycle to be ideal for the small automatic recloser when using instantaneous tripping:

1. Instantaneous first trip followed by high speed reclosure.
2. Instantaneous second trip followed by time delay reclosure.
3. Time-lag third trip followed by time delay reclosure.
4. Time-lag fourth trip followed by lockout.
5. Time-lag on first trip followed by lockout on manual reclosure.

First Operation

The instantaneous tripping characteristic on the first operation is desirable because it insures the protection of small fuse links over a wide range of fault currents. This is the problem involved in extending the reclosing feature to the fuse cutout.[1] To enhance the value of the high-speed first trip, it should be made extremely fast in order to limit the damage to conductors by power arcs. In G. A. Matthews' paper on the "burn-down" characteristics of conductors, he stated that "to prevent burn-down of covered wire and to hold the arc damage within admissible limits, power arcs must be limited to one-half to two cycles (60-cycle basis) over-all time, depending upon the size of conductors and arc current. Bare conductors are less liable to serious arc damage owing to the phenomenon of arc travel and to the self-extinguishing characteristic of arcs on such conductors."[2]

The desirability of high speed reclosure

Paper 47-50, recommended by the AIEE committee on protective devices for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted October 23, 1946; made available for printing November 25, 1946.

J. M. Wallace is section engineer in the switchgear and control engineering department of Westinghouse Electric Corporation, East Pittsburgh, Pa.

after the circuit is cleared was shown many years ago.[3] Experience over a considerable period of time has proved the usefulness of rapid reclosure in minimizing system disturbances and in reducing inrush currents after the outage. The reclosing time on circuits where the small automatic recloser may be used can be made as short as ten cycles with expectation of complete deionization of the flashover region.[4] It is obvious that a 10-cycle outage on lighting loads is so short as to be considered a "flicker" rather than an outage. Most motors will operate through such an interruption with only a small change in speed. Consequently, if the reclosing time is made very short, the line inrush current will be small compared to that which would result for a longer outage period.[5] In addition it is felt that if reclosure after the first operation is not high speed, there is a good probability of retripping an instantaneous recloser because of inrush currents.

Figure 2. Cross section of recloser

Second Operation

The characteristic on the second operation also should be instantaneous as some of the faults will not be cleared on the first operation, and others will be repetitive lightning strokes.[6] Field tests over a number of years have shown that about 80 per cent of all faults are cleared on the first operation and about ten per cent are cleared on the second operation of the protective device. Consequently, if the instantaneous tripping characteristic is maintained for the second operation, an additional ten per cent of the fuse cutout operations can be prevented. The reclosing time after the second operation should be long, however, in order to insure clearing of the fault in the case where the necessary deionization time exceeds that allowed on the first reclosure. Also, if the next tripping operation is to be time delay, a slower reclosing time and larger inrush currents will not interfere with re-energizing the system.

Figure 1. Improved recloser mounted on 4-by-5-inch crossarm

Third Operation

On the third operation the time-lag tripping characteristic is essential to allow sufficient time to blow the fuse link in the protected fuse cutout and isolate a fault beyond it.[7] In addition, it is desirable to insure pickup of the load.[8] In some instances it may allow enough time for burning the fault clear, and in these cases an interruption of the power arc is required before the line can be re-energized successfully. For this reason, the third operation should be followed by time delay reclosure to allow time for mechanical separation of foreign agents such as tree branches.

Lockout and Manual Reclosure

The last operation before lockout should be time lag to insure pickup of the load after the fuse link has blown or tree branch dropped clear. Similar reasoning applies to the tripping characteristics on manual reclosure after lockout. If the fault has been cleared, the time-lag tripping will allow the line to be re-energized. If, however, the fault is still on the line, the recloser should lock out after the first operation to prevent needless contact and oil deterioration.

New Recloser

A new recloser has been developed to meet the foregoing requirements. Its general appearance is shown in Figure 1. In order to meet safety requirements of

direct pole mounting, the recloser is encased in a metal tank which may be grounded. The operating coil is protected by an internal lightning protective gap connected directly across the coil thus eliminating the necessity for external gaps. The mounting brackets are welded to the drawn steel tank and allow use of various types of hangers. The operation counter is mounted in an extension of the top casting in order that it may be seen easily even from the ground. The top cover is held in place by clamps which allow it to be rotated to the most convenient position for manual operation.

Figure 2, a sectional drawing of the recloser, shows the mechanism in its normal current carrying position. The circuit is from the upper line terminal through the coil to one stationary contact, through the moving contact to the other stationary contact, and back to the other line terminal. The armature of the coil furnishes the entire work required for operation of the recloser. On overload it is drawn upward by the coil and compresses the operating spring. As it reaches the end of its stroke, the thrust tube connects solidly with the shoulder on the operating rod and starts the contacts traveling upward. Because of the arrangement of the mechanical linkage of the contact pressure spring, the contact force decreases rapidly as the contacts move upward and drops to zero in about 5/8-inch travel. Consequently, the operating spring will force the moving contact to travel to the end of its stroke as there is no opposing force from the contact pressure spring. This arrangement of the contact pressure spring reduces the work required from the coil to a minimum and helps to attain high speed on tripping. In addition, it helps to insure positive operation

Figure 3. View of integrator and timer assembly

Figure 4. Oscillogram showing timing of operation to lockout. Sections of oscillogram showing open circuit conditions have been deleted

Figure 5. Oscillogram showing interruption on first operation at 1,200 amperes, 8 per cent power factor, 7,200 volts

when only a relatively small operating force is available as is the case with this class of equipment.

On each operation of the recloser the integrating piston is advanced one notch by its mechanism, being held in position by oil trapped by the check valve. After a successful reclosure of the circuit, the integrator will settle slowly to its starting position as the trapped oil leaks away. However, four successive openings will cause it to advance continuously until it breaks the lockout toggle, thus moving the operating level downward to indicate lockout and to hold the contacts in their open position. It is seen that the reclosure is tripfree as it is impossible to hold it closed by means of the operating lever.

As may be seen in Figure 3, the integrator performs the additional function of controlling the timing cycle of the recloser. As with the earlier model, the armature is a relatively close fit in its guiding tube and consequently must force oil in and out of the dashpot thus formed. When the integrator is in its initial position, this dashpot is freely vented through the timing port, as shown by the arrows, thus allowing instantaneous tripping. As there is nothing to prevent immediate flow of oil back into the dashpot, the recloser immediately resets. On the second operation, the timing port is not closed until the last half inch of armature travel, thus again allowing an instantaneous tripping operation. On reclosure, as the timing port has been closed by the integrator, the armature is restrained in its downward motion. Consequently, the contacts will move towards their closed position at a slow rate along with the armature until the contact pressure spring starts to leave its "dead center" position. The rapidly increasing force characteristic of the contact pressure spring causes it to accelerate the contacts rapidly, slightly compressing the operating springs, and gives snap action on reclosing. On the third and fourth operations the vent remains closed so that time lag is afforded on both tripping and reclosing.

To meet the requirements for a recloser utilizing time lag on all operations, the recloser is supplied with a plug in the timing port so that no dashpot venting can take place and all operations both opening and reclosing are time delay. This meets the requirements for substation and main line installations as described previously. In order to change to the instantaneous cycle described in the paper, it is necessary only to remove and discard the plug, an operation readily done in the field at installation.

The recloser utilizes a modified Deion grid to insure interruption at the end of the first half-cycle of arcing. This minimizes oil consumption and reduces wear on the silver tungsten contacts. The contact structure is arranged to give self-aligning action.

Standard current ratings for the re-

Figure 6. Time–current curve for 5-ampere recloser

Note co-ordination with conventional fuse links

closer are 5, 10, 15, 25, and 50 amperes with corresponding interrupting ratings of 150, 250, 375, 600, and 1,200 amperes at 15 kv. The basic insulation level is 95 kv. These ratings are met by the use of five different interchangeable coils for use in the same recloser structure. Coils are protected by a novel type of protective gap mounted under the oil on the coil frame. As the protective gap is thus insulated from ground, it can have a very low breakdown value compared to the 95-kv basic insulation level required for a grounded gap. Because of the low breakdown of the protective gap, very little stress is placed on the coil insulation. As the protective gap is in shunt relationship with the coil, surge currents are by-passed by the coil through the gap and power follow current is interrupted easily by the protective gap and shunted back into the coil. This direct connection of coil and protective gap allows each to help the other efficiently.

Recloser Performance

A complete cycle of recloser operation to lockout is illustrated by Figure 4. Although the current shown is but twice the minimum tripping current of the recloser, the high speed tripping time is only six cycles. Note that reclosure takes place in 13 cycles after the first interruption. Figure 5 shows an oscillogram of an interruption at 1,200 amperes, and it will be noted that total clearing takes place in two cycles. Note that the contacts separate in one cycle and that two half-cycles of arcing takes place. The test circuit has a high rate of rise-of-recovery voltage and the test power factor was eight per cent lagging. On a circuit having a lower rate of rise-of-recovery voltage or with a higher power factor, such as would be encountered on most distribution systems, arcing time limited is usually limited to one-half cycle giving a total clearing time of 0.024 seconds at maximum fault current. Figure 6 shows a time–current curve for the 5-ampere recloser and includes curves for standard fuse links. This shows that they can be protected on the first and second operations of the recloser and blown by the third operation throughout a wide range of current. Thus the co-ordination described in the beginning of the paper is achieved.

Conclusions

Field experience for more than six years shows the advantages to be gained by the use of a small automatic circuit recloser on a-c distribution systems. Co-ordination to extend the reclosing feature to the fuse cutout has proved itself quite valuable. The revised recloser still includes the time-lag of the previous model for co-ordination of reclosers with each other. In addition, by simple field adjustment, the new recloser can be made to co-ordinate with fuses under wider ranges of fault currents than were previously possible.

With the instantaneous tripping characteristic followed by instantaneous reclosing, 80 per cent of the temporary service interruptions now experienced with conventional automatic circuit reclosers will be eliminated effectively. Further advantage of the instantaneous tripping is the reduction of damage to the conductors and the system on temporary faults. These new factors will aid in the co-ordination of radial distribution systems and will increase the benefits obtained from this type of protective device.

Discussion

C. E. Asbury (The Commonwealth and Southern Corporation, Jackson, Mich.): It is encouraging that further progress is being made in oil circuit recloser development. In some of the earlier designs, tripping operations were either all instantaneous or all time delayed. Either of these arrangements usually could be worked in a system to co-ordinate with backup protection but could not be made to select properly when the recloser was used as a backup device or a protected device. That is, it was very difficult to obtain proper selectivity with fuses on the load side of the recloser. In this paper Wallace has pointed out that this type of co-ordination often depended on heat storage in the fuse elements during successive operations of the recloser. The amount of heat stored between successive operations of the recloser may be very small and unreliable for co-ordination purposes, as there is a cooling period of the fuseable element while the recloser is open and as most of the heat dissipation of the fuseable element is due to conduction, which may be quite rapid, depending on the mass and temperature differential of the surrounding metallic parts of the cutout. The necessity for improving the design of the recloser to permit proper co-ordination of fuses has been recognized, and successful application has been made of a number of reclosers having the first one or two tripping operations high speed followed by one or more time-delayed tripping operations. It is encouraging to find another manufacturer of reclosers changing design to incorporate this desirable feature.

As the main purpose of making the first two tripping operations fast is to allow more time between the fast and time-delayed tripping operations for proper fuse co-ordination, why should not the fast tripping operations be designed for 1 or 2 cycles instead of from 2 to 15 cycles as shown in Figure 6? Referring further to Figure 6, a band is shown for the time–current characteristic. Are these bands intended to allow for manufacturing tolerances or for performance variation due to temperature changes or some other cause?

What is meant by the "net time to lockout" time–current characteristic in Figure 6, and how is this characteristic established?

The cycle of operations listed as 1–5 in Wallace's paper are all important, and for most applications are desirable features to incorporate in a recloser. Wallace points out that in certain applications it may be desirable to modify these characteristics to make all tripping operations time delayed to prevent undesirable tripping of a recloser on the first instantaneous operation due to faults on branches that have small fuses. Item 5, which provides one time lag tripping operation when reclosed manually following a lockout, appears to be a new feature in this recloser that is not available in most other designs, and this likewise is a very desirable characteristic. Even though there have been many improvements in the design of reclosers during the few years of their development, there are still a number of quite important characteristics that should be given consideration in their design for additional improvement. These additional desirable characteristics may be listed as follows:

1. The original designs were intended for application on rural lines having relatively low short-circuit capacity. The interrupting rating for this class of recloser is too low for very general application on distribution circuits. With growing demands which will require larger supply banks and heavier power sources, the short-circuit capacities for distribution as well as for rural service are quite likely to increase considerably in the next few years. This will limit further the application of reclosers, unless their interrupting ratings are increased. It would be interesting if Wallace could point out how much the interrupting capacity could be increased, if any, by permitting the recloser to trip one time on an instantaneous operation, reclose at the end of a time delay of approximately 30 cycles, and then, if the fault is persistent, trip on one time delay operation and lockout. A recloser adjusted for this type of operation might be used in a number of applications where the interrupting rating is somewhat higher than those stated in the paper.

2. The continuous current ratings for the class of recloser described in the paper are too low, especially for application of the lower voltage distribution systems such as 7,200 volts and less.

3. The time delay used for tripping has not always been found consistent and reliable enough in reclosers in general. As these reclosers must select with relays and fuses, they should have a time–current characteristic at least as accurate as a fuse, and preferably approaching that of an overcurrent relay. The recloser described by Wallace uses an oil dashpot for timing, which undoubtedly will be affected appreciably by variations in temperature. In addition to using oil dashpots, some manufacturers have used timing escapements, which are in general inconsistent and unreliable when produced on a mass basis and usually are subject to hanging and binding, which may cause failures to reclose or trip. Oil dashpots, air bellows, and escapement methods of timing were attempted in the earlier design of protective relays and found to be unreliable and were superseded by more accurate timing arrangements. It would be very desirable if a more accurate and reliable timing principle could be selected for the tripping function of oil circuit reclosers. It would be interesting if Wallace could point out what variation due to wide ranges in temperature (100 to 0 degrees Fahrenheit) he has found in the time–current characteristic of the recloser. Oil circuit reclosers could be applied more intelligently by the users if the manufacturers would publish time–current characteristics showing the effect of temperature on their timers used for tripping. This could be represented by a band on the time–current curves, so that proper allowance could be made by the user when the device is co-ordinated with the time–current characteristics of fuses and relays.

4. The application of reclosers would be simplified, and probably increased, if a more flexible arrangement could be provided for their settings. A reliable external pickup adjustment and time lever setting for shifting the time–current characteristic is desirable to provide more flexibility in the co-ordination of various makes of reclosers with various makes of fuses and relays.

5. Most reclosers are designed with solenoids connected in series with the line, so that overcurrent in the solenoid operates the plunger. As the plunger moves into the coil, the impedance of the coil changes which makes it impractical in most instances for testing on a low voltage test source. It is quite difficult to check the pickup or time–current characteristics of these devices on high voltage test sources, and it would be very desirable if the design of the timing device could be such as to permit testing in the field with a low voltage test source using ordinary relay testing equipment, such as a load box and cycle counter.

It is hoped that these desirable characteristics can be incorporated in the design as a result of advancement in the art and, with the aid of increased production, that they will not necessarily result in any appreciable increase in price.

Figure 5 of Wallace's paper shows one interruption of 1,200 amperes at 7,200 volts which occurred in about 2 cycles. Have any tests been made on the recloser at 1,200 amperes on 15 kv where it was required to produce its complete sequence of two fast and two time-delayed tripping operations to lock out?

G. Fred Lincks (General Electric Company, Pittsfield, Mass.): Wallace's paper points out the benefits that will be obtainable when reclosers and fuses can be co-ordinated, so that the reclosers clear all nonpersistent faults on the entire circuit and so that the main line sectionalizing fuses, the branch fuses, and in some cases even the transformer fuses operate only on persistent faults to isolate a small section of the circuit. This will be spoken of hereafter as the "modern concept" of distribution overcurrent protection. In addition to the improved service continuity attainable, he stresses the value of the initial instantaneous opening in the prevention of line burn-down. However, in his recommendations on the application of reclosers, he would apply reclosers so that the benefits of the modern concept are obtained only at the outer end of the circuit and on the small percentage of the branches which are long enough to justify the use of reclosers.

Wallace recommends the use of time delay opening on all operations on the first two or three reclosers from the power source on the main feeder and, we assume, the use of fuses on all of the many short branches connected directly to the main feeder, with these fuses co-ordinated to clear both nonpersistent and persistent faults before operation of the recloser. He premises these recommendations on a desire to avoid power interruptions to a majority of the consumers on the circuit resulting from faults occurring on short single-phase branches. He does not mention, and may have overlooked, that with the modern concept of fuse-recloser co-ordination, a fault on these single-phase branches causes only one, or possibly a succession of two or three, momentary power interruptions before the fault clears itself or the branch fuse blows and also that these momentary outages affect about one third of the consumers on a rural 4-wire circuit. One third of the consumers are affected only by faults on

branches connected between the first and second reclosers, and the number of consumers subjected to momentary power interruptions is much less for faults on branches beyond the second or the third recloser. He indicates that possibly an influencing factor in guiding his proposal is the inability of higher rated reclosers, when used close to the power source, to protect associated lower rated fuses used at the branch junctions. Such protection of the branch fuses is necessary on the initial two instantaneous openings with the modern fuse-recloser co-ordinated setup. But, why use small fuses, unless this is a limitation of Wallace's recloser.

It has been shown[1] that automatic reclosing equipment for protecting short branches affords very little benefit to the over-all service continuity of the whole system because of the few consumers on the branch who are affected by the prolonged outages caused by nonpersistent faults on the branch. However, the individual consumers on these branches benefit from automatic reclosing on the branches, and relatively large savings can be effected in the expense for restoring service and in the automotive miles traveled.[2]

Generally, application limitations or requirements make it necessary to locate reclosers from 10 to 15 to 25 miles apart on the main feeder. Thus the first two or three reclosers from the power source control long sections of the 3-phase feeder plus the numerous short single-phase branches connected thereto. The combined mileage of the feeder and these branches represents at least 20 to 25 per cent of the total mileage on the circuit and an equal percentage of the consumers. Thus, with Wallace's scheme, at least 20 to 25 per cent of the consumers would get an inferior grade of service continuity, and the restoration expense would be increased in order that the other consumers need not be subjected to the additional momentary power interruptions from faults occurring on only one third or less of all the short single-phase branches connected to the main feeder.

With reclosers spaced 15 to 25 miles apart, the problem of locating faults quickly makes it imperative to sectionalize further the main feeder. With the modern concept, fuse–recloser co-ordination will permit this additional sectionalizing of the main feeder between reclosers, using fuses which melt only to clear persistent faults in the section they protect. Wallace's scheme does not permit such advantageous sectionalizing and, thus, would impair further the service continuity to a majority of consumers on the circuit below that possible under the modern concept.

Fuse–recloser co-ordination studies made on four or five rural circuits with different types and makes of reclosers operating on the modern concept make very understandable the limitations Wallace faced in applying his recloser. However, these studies indicate that the co-ordination of the reclosers with branch fuses, either close to the source of power or out on the line, is entirely practical if the reclosers have the right characteristics. Also, with the right characteristics it is practical to fuse sectionalizing points between reclosers and to connect these section fuses in series with branch fuses, both of which are protected properly by the reclosers. In addition it is possible to co-ordinate with internal fuses found in both early and recent vintages of distribution transformers.[3]

Another apparent oversight in Wallace's recommendation that the first two or three reclosers from the power source on the main feeder should have all time-delay openings is that the advantage of preventing line burn-down on the backbone of the feeder was not considered. Initial instantaneous opening, in preventing some burn-downs of the main line, avoids long outages to a majority of the consumers.

Thus, while the elimination of a few momentary power interruptions to a number of consumers is advantageous, as suggested by Wallace, it appears that the sacrifices in impaired service continuity, in increased restoration expense, and in the possibility of more line burn-downs on the backbone of the system are too high a price to pay for just preventing a few clocks from showing the red flag. Thousands of reclosers which operate instantaneously have been performing successfully for years in clearing nonpersistent faults at all locations on rural lines. A few may have locked open by inrush currents from motor starting after prolonged outages, but not following a momentary opening as is suggested by Wallace. Therefore, the best distribution overcurrent protection practice appears to be that of applying all fuses and reclosers on the circuit in accordance with the modern concept and making certain that the characteristics of the recloser permit the full advantages to be obtained with such an application.

Leonard M. Olmsted (Duquesne Light Company, Pittsburgh, Pa.): The recloser described in this paper has characteristics far better suited to the requirements of distribution circuit protection than its predecessor described in the 1941 paper.[1] It shows recognition of certain difficulties encountered by distribution engineers and marked improvement in several respects. Though small self-contained devices of this sort can not be expected to satisfy all the requirements of all possible applications, it seems probable that further consideration of application problems may encourage the development of reclosers suitable for use in many places where this recloser would not be satisfactory.

In the first place, the paper discusses the desirability of characteristics such that the recloser will operate initially fast enough to protect small fuse links and to prevent the burning down of covered wire. Before lockout, however, the accumulated effect of successive operations must be sufficient to operate the largest fuses on the load side of the recloser, as otherwise a faulted transformer or branch line could hold a large portion of the circuit out of service. Distribution engineers frequently select a minimum fuse size determined as a compromise between transformer protection and unnecessary operations caused by lightning surges or customers' trouble, and use this size on the two or three smallest sizes of transformers. For somewhat larger transformers, the fuse size is increased more or less as a function of the transformer current rating. In planning the application of reclosers to a specific distribution circuit, it is not unusual to find transformers ranging in size from $1^1/_2$ to 15 kva with several sizes of primary fuses, possibly also line fuses, with which the recloser is expected to co-ordinate successfully.

At distribution voltages of 7,200 or higher, it may be that only a small range of fuse ratings is encountered and that such recloser characteristics as those of Figure 6 in the paper are satisfactory. On 2,400–4,160-volt circuits, however, it is not uncommon to find fuses ranging from 5 or 10 amperes up to 25 or 30 with which the recloser must co-ordinate on the basis of protecting the smallest fuse on its initial operation and clearing the largest fuse before lockout. Assuming that its time–current characteristics are proportional to Figure 6, then co-ordination with a 10-ampere fuse would require a recloser not larger than about 40-ampere rating, and such a recloser could not clear reliably a larger fuse than perhaps 20 amperes. The ratio between maximum and minimum fuse sizes appears to be two to one, where the application requirements are more on the order of four to one. From this viewpoint, it would seem that the new recloser, though it is superior to its predecessor, still is imperfectly suited to the requirements for extensive use on the lower voltage distribution circuits, where a larger recloser with greater spread between initial operation and lockout is desired. This problem was recognized several years ago by at least one industry association which urged the development of larger reclosers for such applications.

Another problem encountered in the application of reclosers to lower voltage circuits is safety to operating personnel. It is customary to work on lines and pole-mounted equipment energized at voltages up to 5,000 without interrupting service, by applying protective covering to all "live" conductors and equipment. In this respect, the new recloser shows a marked improvement over the earlier design, in that the top casting is insulated from line potential. The lineman still has limited access to operate the device by hand, however, and must climb close to the top casting to read the operation counter. Under these conditions, interrupting capacity is an important factor in safety to personnel; the present maximum of 1,200 amperes greatly impedes the application of reclosers to 2,400–4,160-volt circuits.

After extensive investigations, one large power company has concluded that the length of rural 2,400–4,160-volt circuits must be restricted to approximately 20 miles, if the desired degree of service continuity is to be attained. Because of sparse loading, many circuits must exceed this length and can be expected to provide satisfactory service continuity only if automatically sectionalized in such a manner that no fault can involve more than 20

miles of circuit. Many reclosers could be applied advantageously in such a program, provided they can be designed with a suitable time–current characteristic and sufficient interrupting capacity.

1. AN AUTOMATICALLY RECLOSING BREAKER FOR CO-ORDINATING DISTRIBUTION SYSTEMS, J. M. Wallace, H. L. Rawlins. AIEE TRANSACTIONS, volume 60, 1941, December section, pages 1021–4.

R. F. Quinn (General Electric Company, Schenectady, N. Y.): Wallace's paper, and particularly the characteristics claimed for the recloser, have been studied with regard to the actual problem of co-ordinating protective devices on a rural distribution feeder. As a result of this study, the following questions have arisen:

1. What does the shaded area shown on the recloser time–current curves in Figure 6 indicate?

2. What is the effect on the instantaneous opening time–current curve and on the time delay opening time–current curve of ambient temperatures ranging down to −10 degrees Fahrenheit and up to 120 degrees Fahrenheit?

3. If the shaded area referred to in question 1 does not include over-all service temperature effects, how should the user factor these effects to obtain proper co-ordination of fuses with reclosers as discussed by Wallace under the heading, "Improved Characteristics Needed"?

4. What is the resetting time of the mechanism after the first opening, if it is assumed that the fault is cleared by the one operation? What is the resetting time after the second and third openings, assuming successful reclosure in either case?

It is believed that Wallace will recognize that the answers to these questions are very pertinent to any sound engineering application of reclosers for rural line sectionalizing. It is better for the user to evaluate these factors with full knowledge of their effect on the ultimate co-ordination that will be realized, than to overlook these effects and run the risk of malfunction of the intended scheme of operation.

Max W. Rothpletz (Rural Electrification Administration, Washington D. C.): It is gratifying to note the operating characteristics which are incorporated in the oil circuit recloser described by Wallace. The sequence of two fast and two time-delayed openings, together with the time-lag tripping on manual reclosure, should make this a very desirable recloser for sectionalizing rural power lines.

The problem of co-ordinating fuses with oil circuit reclosers has been a serious one on rural circuits; co-ordination of distribution transformer weak links with reclosers has been particularly difficult to obtain. For example, the weak link in one make of 3-kva transformer has a time–current characteristic such that the 5-ampere recloser described in the paper will trip on time delay before the link will blow on currents less than about 21 amperes, or the recloser would lockout, in accordance with the curves shown, before the link fails on currents less than about 15 amperes. If the time delay were increased, so that the recloser would open in about 10 seconds at minimum tripping current, this co-ordination problem would be largely solved.

Our data on inrush currents are not complete enough to warrant drawing any definite conclusions; however, it appears that a time of at least two seconds at minimum tripping current is required to permit the recloser to pick up loads.

W. J. Rudge (General Electric Company, Pittsfield, Mass.): Under the paragraph headed "New Recloser" the author states, "In order to meet safety requirements of direct pole mounting, the recloser is encased in a metal tank which may be grounded. The operating oil is protected by an internal lightning protective gap connected directly across the coil, thus eliminating the necessity for external gaps."

I would like to ask the author to explain how a protective gap which is placed directly across the series coil, and can only limit the impulse voltage across the coil, eliminates the necessity for lightning protection of the major insulation of the recloser, particularly since the author points out that the tank may be grounded.

If flashover takes place on the load side bushing of the recloser, the recloser itself would be expected to clear the fault. However, if flashover takes place on the source side bushing of the recloser, it would be necessary to depend on some other recloser or fuse nearer the power source to clear the fault. This latter case would cause an interruption to a part of the system which could be avoided by proper lightning protection of the recloser.

Roy M. Smith (Railway and Industrial Engineering Company, Greensburg, Pa.): The operating characteristics of the new automatic circuit recloser are most interesting. However, we cannot agree that the cycle of two instantaneous trips followed by two time lag trips to lockout is by any means "ideal."

While everyone will agree that an instantaneous trip followed by a fast reclosure is desirable to prevent the unnecessary blowing of fuses, there seems to be little justification for the second instantaneous trip. An inspection of Figure 6 of the author's paper indicates some margin for fuse co-ordination between the first instantaneous trip and the third time lag trip, although apparently only one or two fuse ratings could be accommodated—and then for only a portion of the current range. As the first trip is not particularly fast, as compared with the damaging time for a fuse, it is difficult to see how the second instantaneous trip can be made to co-ordinate, for it will be faster than the fuses for small currents, and slower for larger currents.

It would appear that an improvement in operating duty cycle might be the following:

1. Instantaneous first trip followed by high speed reclosure;

2. Time-lag trip followed by time-delay reclosure;

3. Time-lag trip followed by lockout.

With such a duty cycle, it would be possible to protect one or two fuses for transient faults and to blow them on permanent faults without an unnecessary lockout. At the same time, permanent faults on an unfused portion of the circuit would be given two opportunities to burn clear. With such a duty cycle the system would be subjected to less shock, and yet full protection would be obtained.

We note that the timing characteristics of the new recloser appear to be somewhat erratic. While the time curves in Figure 6 are shown as a band, similar to fuse curves, they apparently should be considerably wider to accommodate the variations normally expected with a dashpot timer.

For example, the paper indicates that the oscillogram in Figure 4 was taken on a 5-ampere recloser at 20 amperes, but the times shown do not fall within the bands of Figure 6. The time for the first two instantaneous trips are shown as 0.1 second, but the curve in Figure 6 shows a time between 0.06 second and 0.073 second, or an average of 0.067 second. This is an error of 50 per cent.

Likewise, Figure 4 shows a time lag of 0.3 second for the third trip and 0.4 second for the fourth, although Figure 6 gives an average time of 0.52 second or an error of 42 per cent in the worst case. Perhaps the inconsistency is due merely to temperature error, but some explanation would be desirable, as it would be difficult to co-ordinate the recloser with a fuse from the data given.

A. Van Ryan (Kyle Corporation, South Milwaukee, Wis.): The development of automatic circuit reclosers came about through the knowledge that by far the greatest majority of faults occurring on rural distribution systems are of a transient nature. These faults, once cleared, permit automatic restoration of service.

Fuses do not have the ability to interrupt automatically and restore service indefinitely, and, as pointed out by Wallace, cannot be depended on to co-ordinate with automatic circuit reclosers having single time–current characteristics.

However, low revenue does not warrant the cost of automatic reclosers on small branches extending from the main lines as well as from the main branch lines, and thus inexpensive fuse cutouts are used at these points on the system.

To permit the use of fuses and yet provide complete protection, the automatic circuit recloser having dual time–current characteristics was developed. A recloser of this type was described to the Institute in 1945.[1] Such reclosers have been in use for somewhat more than two years and have proved their ability to interrupt and restore service upon the occurrence of transient faults and to isolate permanent faults to a small locality. In a distribution system so arranged, the transient faults are cleared, and service is restored, by the automatic recloser; the permanent faults are cleared and isolated by the recloser or the fuse, depending upon which one of these protects the faulted section.

Thus, although it may seem desirable to protect the main lines with automatic reclosers having delayed time–current characteristics to prevent short interruptions of service and thus give the main lines so-called "backbone," it appears that this will cause unnecessary blowing of fuses on the small branches of the main lines.

The reason for this, as pointed out, is that fuses and single time–current characteristic reclosers will not co-ordinate with one another over a wide enough range of fault currents. It is, in fact, the reason why dual time–current characteristic reclosers were developed. In other words, what is good for the branch lines is good for the main lines. Thus, it appears that dual time–current characteristic automatic reclosers must be used throughout, if fuses are to be used in conjunction with them. That part of the system protected for its transient faults by an automatic circuit recloser by necessity will have an outage of very short duration when a transient fault occurs.

Automatic circuit reclosers are used in series on distribution systems. For this reason they must co-ordinate with one another as well as with the fuses they protect against transient faults.

If, after a permanent outage, a recloser has only one retarded time opening characteristic, all related reclosers having substantially instantaneous time–current characteristics will operate until they too fall into retarded time characteristics. If a dual time–current recloser not so arranged for its first operation after manual reclosure is substituted, it often will reduce the current, during the time of the first two reclosures, to such a value that it is below the value which will cause the backup recloser to operate. Besides this, it has in reserve another retarded characteristic opening, should the first one fail to pick up the starting load. It is, therefore, not clear that this feature of the described recloser is desirable.

Wallace is to be congratulated on the work he has done on his recloser, so that it too has satisfactory tripping characteristics for co-ordination with fuse cutouts.

1. Improved Fault Protection for Rural Distribution Systems, A. Van Ryan. AIEE Transactions, volume 64, 1945, May section, pages 261–3.

J. M. Wallace: Asbury suggests that the speed of the first tripping operation be increased. It should be pointed out that in small automatic reclosers, all of the energy to operate the recloser is taken from the circuit by means of a series coil. On low currents, there just is not sufficient energy available to operate the recloser in the short time that Asbury suggests. Of course, by going to additional complications, high speed tripping might be realized, but this in turn probably would result in a higher cost for this type of device. It is believed that in general the operation of the device is satisfactory for most locations and, that the increased cost would not be welcomed by the user, even though it did result in somewhat better characteristics. In some locations the increased cost would be justified, and perhaps a new device will be developed to meet these requirements.

The second question asked by Asbury is the reason for the bands on the time–current characteristics curves. These bands are intended to show manufacturing tolerances.

The third question is about the "net time to lockout" characteristic. The net time to lockout consists of the sum of the tripping time at any current for all four operations. In other words, it represents the total time of flow of fault current to lock out the recloser. Contrary to Asbury's statement that the heat loss from a fuse link is extremely variable, experiments have shown that on larger sizes of fuse links, above 5 amperes, with interruptions of less than two seconds on each flow of fault current, there will be less than 5 per cent of the heat lost. Consequently, in considering this problem, it is possible to co-ordinate over a somewhat wider range of current by considering the heat that is stored in the fuse link.

Asbury asked whether the interrupting rating of the recloser could be increased by limiting its operation to two interruptions. For the recloser described in the paper, no increase could be realized, and it is the author's belief that the same is true of other reclosers. In order to build a recloser which will operate satisfactorily, it is necessary that the interruptor be cleaned completely or flushed after each interruption, and, consequently, the duty on the interruptor is not reduced greatly by limiting the number of interruptions.

Asbury asks whether tests have been made at 1,200 amperes and 15 kv. In reply we would state that the recloser has been tested successfully at 1,200 amperes, 20 per cent power factor, and with 13,800 volts across the single pole.

Lincks discusses the so-called modern concept of distribution overcurrent protection. It should be noted that the modern concept was introduced first by H. L. Rawlins and the author of the present paper in 1941 when a recloser using all time lag characteristics was described to the Institute. At that time it was shown how a fuse link could be protected on its first operation and blown before lockout of the recloser by means of stored heat in the fuse. This method of co-ordination is satisfactory over a range of current which admittedly is somewhat limited when compared with the combination of instantaneous and time lag trips shown in the present paper. However, the range of current is satisfactory for many locations and will take care of many of the short branches, which Lincks states will not be protected adequately.

Also, Lincks' discussion overlooks the number of short branches which require no fusing and the number of short branches which can be co-ordinated with the time lag reclosers. He concludes with a statement that at least 20 to 25 per cent of the consumers would get an inferior grade of service continuity. Perhaps this should be restated that 5 to 10 per cent of the consumers would get an inferior grade of service continuity rather than the 25 per cent, as he has overlooked the afore-mentioned conditions. The author still believes that, in order to prevent an inferior grade of service continuity of the whole system by having momentary outages experienced by simultaneous tripping of reclosers and by additional operation and lockout of reclosers, it is worth having a somewhat inferior grade for the 5 to 10 per cent of the consumers mentioned. After all, this so-called inferior grade of service is still as good as that which these customers have been getting for the last several years. Consequently, it is hard to believe that very many complaints would be heard from these particular customers, especially as more than half of the system would have an increased class of service at the expense of this 5 per cent. It still is believed that the "backbone" of the system should be kept stiff.

Olmsted practically confines his discussion to 2,400–4,160-volt circuits. Admittedly, circuits of this nature are higher current circuits than the 7,200-volt circuits on which this recloser is expected to operate. For these lower voltages, the current rating should be increased somewhat and the interrupting requirements probably should be increased also. Whereas we agree that it is desirable to develop reclosers for this service, so far it has not been proved that their application would result in a rather wide market. It should be realized that, with devices of this type, the development and tooling is necessarily quite expensive, and in order to produce any reasonable cost it is necessary that the number of units produced be high. Perhaps, as more users become familiar with the problem set forth by Olmsted and begin to accept his viewpoint, the market for such a device will grow to a point where a manufacturer will become interested in developing a device specifically for these voltages.

Quinn questions the effect of ambient temperature on the recloser. The temperature effects are not critical over a range from 40 degrees Fahrenheit to 100 degrees Fahrenheit. Most of the operations of the recloser will take place in these temperatures as found in the United States. These are temperatures experienced during the lightning season. If sufficient margin is allowed between the fuse links and recloser, proper operation will take place over a wider temperature range. Although it is realized that the recloser will change time characteristics with temperature change, it also should be realized that there will be corresponding change in the fuse link characteristic. This will help to offset the difficulties pointed out by Quinn.

Quinn questions the resetting time of the mechanism after a successful reclosure. This time is approximately 15 seconds per step, which means that after one reclosure, 15 seconds is required to reset, and after three interruptions, 45 seconds is required.

Rothpletz has pointed out the difficulty of co-ordinating the reclosers with the so-called "weak link" in the transformers. This co-ordination problem is serious, and it is agreed that attention must be given to the subject. However, an immediate solution is readily available to the operators by use of a larger size of recloser. If the 3-kva transformer will not co-ordinate with a 5-ampere recloser, it is possible to use a larger rating of recloser where this problem must be solved.

Rothpletz mentions the data on inrush current and states that for the recloser to pick up load it ought to take at least two seconds at minimum tripping current. The earlier recloser which preceded the one in the present discussion had time–current curves which met this requirement, and to the best of our knowledge there never has been any operating trouble experienced in picking up load. The present recloser meets Rothpletz's requirements in that it has exactly two seconds at its minimum tripping current for load pickup.

The discussion by Rudge is correct

in that the protective gap across the coil does not eliminate the necessity for lightning protection of the distribution circuit or of the recloser. However, the paper did not infer that such protection was unnecessary but stated that the coil itself is furnished protection, which is superior to that supplied by external lightning gaps. External gaps or arresters must meet the basic insulation level of the system, and so they permit far higher surge voltages to appear across the coil than are experienced when the internal coil protective gap described in the paper is used. However, this internal gap is purely for the purpose of preventing surge voltages on the coil itself and obviously has no effect on the over-all system.

The discussion presented by Smith contained two principal points. The first is a question of the need for the second instantaneous trip. The need for this second trip is occasioned by repetitive lightning strokes. Operating experience and lightning studies both have indicated occasions when lightning strokes will take place in the same area in fairly rapid succession. Because of the length of the time required for a recloser to recycle to its initial position, about 10 seconds, it is desirable to have two chances of rapid clearing of the temporary fault. Smith's second point is that the recloser is inconsistent in its time–current characteristics. He refers to the oscillogram, Figure 4, where there is a variation between the operating time of the recloser on its first and second and its third and fourth operations. However, when variations in asymmetry of the different operations shown on the oscillogram are taken into account, the actual variations fall within those shown in Figure 6.

The discussion by Van Ryan is similar to that of Lincks in that he argues that instantaneous tripping should be used on all reclosers rather than as suggested by the author. However, Van Ryan does not present any new evidence which has not been taken into consideration.

Van Ryan states that the recloser ought not to have a time-lag operation when it is being closed after a lockout. He makes this statement on the basis that it is necessary to get co-ordination between main line reclosers, and he adds that the two instantaneous reclosures may be sufficient to reduce the line inrush current to a point at which it can be handled without the necessity of using time lag on the recloser. Experience with tests in the field have shown that this is not the case. In one test, after a 1/2-hour outage, an instantaneous recloser tripped or "chattered" approximately 15 times before the line was re-energized. This certainly indicates the need for time lag on re-energization of the line. In turn, if time lag is used, the recloser will cause an instantaneous recloser preceding it to trip out. In fact, a 5-ampere time-lag recloser can cause a 25-ampere instantaneous recloser to trip. This is one more reason why it is desirable to use time-lag tripping for the backbone of the system in order to prevent such useless operations when re-energizing the system.

Can the Trolley Coach Compete Economically With the Gas or Diesel Bus Where No Overhead Facilities Exist?

J. H. GAUSS
NONMEMBER AIEE

Synopsis: Each type of local transit vehicle has its proper place in the picture of modern transit. This position is determined by sound economics, including complete depreciation on all equipment and facilities. The attractiveness of trolley coach service and its corresponding low operating cost enable this type vehicle to compete favorably with either the gas or Diesel bus even though new power and distribution facilities are required.

MANY factors affect the location of the nerve center of our modern city, one of the most important of which is its urban transit system. Without adequate local transit service, the flow within the city stops. The congestion of cars and more cars clogging streets, parking lots, and garages is one of the first reasons business men shift to new locations. A business ceases to be one, if people cannot get to it. You have seen business districts shift within a city. What once was the heart of a growing city now may have comparatively little value. The heart has shifted to a more desirable location.

Superhighways and freeways have been built and expanded to improve approaches to the city. Actually, streets within the city are fixed basically and do not lend to this improvement. The result is that the external highway improvement adds to the downtown traffic congestion.

Of late, people have become more aware that the problem is basically one of moving people, not vehicles. The search has been for transit equipment that will move people with an economic utilization of available street space.

Selection of Proper Vehicle

In selecting the proper transit vehicle, many widely different factors must be considered, ranging from public preference to fundamental economics. The public's interest in this problem is that they have a short wait for a transit vehicle and that it takes them safely, quickly and quietly to their destination. Public officials and local business men are interested in that the transit system takes them and their workers to their stores and factories and then maintains a rapid turnover of shoppers to the business districts. The transit operators are interested in supplying the above service at a reasonable profit to themselves.

Combining all of these varied requirements of a transit service, there remains the problem of selecting a vehicle that best will suit the desires of all people concerned. Our present consideration is the economics of this operation.

Each of the standard existing types of urban transit vehicles, namely the mechanical bus, trolley coach, Presidents' Conference Committee cars, and rapid transit trains, has its proper economical application. Primarily this application depends upon the density of traffic to be handled. Those familiar with New York City have seen or have been a part of the terrific crowds handled by the subway system. It is difficult to imagine any other vehicle that would move this volume of people adequately. It would require 20 4-lane highways to handle this crowd were they to move by private automobile. This is based on the national average of 1.7 people per car. Those familiar with Washington, D.C., Boston, Mass., or Pittsburgh, Pa., know what a PCC car can do and how many people can be crammed into it during the rush hour. Again, it is hard to imagine smaller vehicles doing that job. If these people all traveled by private automobile, it would require a 9-lane highway to handle the raffic that is now handled by carline.

The Trolley Coach

The trolley coach's economic field of service is those trunk lines that do not justify PCC car operation but do justify a large size vehicle (37–44 passengers). There is another way of expressing this

Figure 1. A trolley coach operating in Kansas City, Mo.

Paper 47-45, recommended by the AIEE committee on land transportation for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted October 30, 1946; made available for printing December 6, 1946.

J. H. Gauss is with the General Electric Company, Erie, Pa.

Figure 2. A trolley coach operating in Denver, Colo.

traffic density bracket. Where a rush hour headway of from two to ten minutes is required, the trolley coach is the most economical transit vehicle. There is still another yardstick. Where a traffic density of from 400 to 2,000 passengers per hour is to be handled, the trolley coach is the most economical vehicle. One trolley coach line can handle the people that a 7-lane highway normally handles by private automobile. For lines of lighter service than those listed above, the mechanical bus is best suited.

With the foregoing background as a general installation guide, one gets a rough idea as to which vehicle to consider most seriously when studying vehicle application to various lines. Under no circumstances can any guide or rough yardstick of this sort be applied to a specific line for the final and definite vehicle selection. A very complete traffic study followed by a simple economical analysis of the proposed vehicle applied to each line is the only sure way of assuring economy of service.

As a means of illustration, we can assume a line in an average American city, ten miles long round trip. A traffic study has indicated that this line requires 44-passenger vehicles operating on a 4-minute rush hour headway. The problem is "Which vehicle can serve this line most economically?"

Number of Vehicles Required

The first step is to determine the number of vehicles required for the line. Table I indicates that 14 44-passenger trolley coaches are required to handle the traffic. To do the same job, 16 44-passenger mechanical busses would be necessary. Because of normal maintenance, wrecks, reconditioning, and so forth, two spare trolley coaches, or three mechanical busses should be purchased, making the total number of vehicles required 16 trolley coaches or 19 busses. Table II indicates the annual number of miles, hours, and passengers handled by each type of vehicle.

The basis of comparison used in Tables I and II bears explanation. All trolley coach data for this entire study were taken from a report published in Bulletin 707 by the American Transit Association in July 1946, covering the operation of large size trolley coaches by 24 transit companies in 1945. This bulletin gives a very accurate set of figures for up-to-date trolley-coach operation.

No such comprehensive data are available for large size mechanical busses. However, the figures used in this study are all based on those of actual operation of large busses. You will note that where it requires but 14 trolley coaches for revenue service, it requires 16 busses. The trolley coach is able to maintain a faster schedule speed in similar service than that of a large size bus because of its almost unlimited power availability for acceleration. The electric motor in the trolley coach operates at between 150 and 200 per cent load for a short period of time during acceleration, making possible a faster and smoother coach pickup and enabling operation at a faster schedule speed. On the other hand, a 44-passenger mechanical bus with seated load is sluggish getting under way, especially if operating on a slight up-grade and does not have the reserve power required to hold its place with other traffic.

In addition to the fact that the trolley coach is inherently a faster accelerating vehicle, other features of its construction assist it in maintaining a faster schedule speed. For example, the trolley coach generally has a 30 per cent wider aisle and wider doors than mechanical busses, enabling the movement of passengers on and off the coach to be speeded up considerably, thereby reducing stop time and increasing schedule speeds.

For these reasons, the schedule speed of the bus in this report is assumed to be ten per cent less than that of the trolley coach. This has the effect of requiring more busses to do a given service than trolley coaches, which has been borne out on many properties.

Table I. Number of Vehicles, Miles, and Hours

	Hours	Head-way	Trolley Coaches	Vehicle Miles	Vehicle Hours	Busses	Vehicle Miles	Vehicle Hours
Weekdays								
A.M. peak	2	4	14	300	28	16	300	32
P.M peak	2	4	14	300	28	16	300	32
Base	14	6	10	1,400	140	11	1,400	154
Night	6	16	4	225	24	4	225	24
				2,225	220		2,225	242
Sundays and Holidays								
Base	16	8	7	1,200	112	8	1,200	128
Night	6	16	4	225	28	4	225	24
				1,425	140		1,425	152

Average schedule speed: trolley coach—10.6 miles per hour; bus—9.5 miles per hour.

Table II. Annual Vehicle Miles and Hours

	Days	Miles: Trolley Coach	Miles: Bus	Hours: Trolley Coach	Hours: Bus	Passengers: Trolley Coach	Passengers: Bus
Weekdays	308	685,000	685,000	67,700	74,600	5,110,000	4,600,000
Sundays	52	74,000	74,000	7,280	7,900	552,000	497,000
Holidays	5	7,100	7,100	700	760	53,000	48,000
Total	365	766,100	766,100	75,680	83,260	5,715,000	5,145,000

Trolley coach—7.46 passengers per mile; bus (ten per cent less than trolley coach)—6.71 passengers per mile.

Most trolley coach operators maintain 2.5 to 7 per cent spare trolley coaches. In this study we have used two spare coaches, or 14 per cent, which is high. As more vehicles were applied to other lines this percentage would reduce in favor of a reduced first cost. We have included three spare busses, or 18 per cent, which is also high by about the same ratio. Fifteen per cent spares for bus operation is normal.

A recent study made of 11 properties disclosed that these properties maintained an average of 2.4 per cent spare trolley coaches and 15.3 per cent spare busses. Seattle, operating 307 trolley coaches, maintain only 2.6 per cent spares. Similarly, they operate approximately 300 busses and maintain 12 per cent spares. For our small operation, two spare trolley coaches and three spare busses seem reasonable.

The miles and hours figures of Table II were obtained from Table I. The ATA bulletin, previously referred to, stated an average passenger loading of 7.46 passengers per mile which results in 5,715,000 annual trolley coach passengers.

Time and again on properties where trolley coaches have replaced busses, passenger revenue has increased materially. Where trolley coaches have replaced street cars and busses have replaced street cars on similar lines, the increased riding on the trolley coach lines has been greater than that on the bus lines. Because of the long life and constant operating characteristics of the trolley coach, it is able to hold its increased revenue through its entire life which is not the case with a bus. Further, the trolley coach, having wider aisles and being a more roomy vehicle over-all, is able to carry approximately ten per cent more people during rush hour than a similar seating capacity bus. These combined characteristics enable us to justify a ten per cent minimum revenue differential in the favor of the trolley coach; consequently there is a difference in annual passengers carried between the two vehicles.

As a summary of the study thus far, we find that to handle this 10-mile route, it requires 16 trolley coaches operating 766,100 miles and carrying 5,715,000 passengers per year. To do the same job, it requires 19 busses operating 766,100 miles and carrying 5,145,000 passengers per year.

Investment

The next factor to consider is the investment required for each type of operation. Table III covers the trolley coach investment and Table IV the bus investment. All costs are as of September 1946; so they are comparable to each other. The bus and trolley coach cost are averages of bids of seven and four builders, respectively, on an actual installation.

Table III. Trolley Coach Investment

Capital Investment	
16 trolley coaches at $16,300.00 (14 revenue service + 2 spares)	$261,000.00
5 miles 2-way overhead	89,000.00
5 miles 2-way feeder	14,440.00
1 1/2 500-kv substations	56,000.00
1 garage and facilities	40,000.00
Total	$460,440.00

Table IV. Bus Investment

Capital investment	
19 busses at $15,300.00 (16 revenue service + 3 spares)	$290,500.00
1 garage and facilities	60,000.00
1 bus storage garage and maneuvering area	60,000.00
Total	$410,500.00

The trolley coach substation cost is worth a comment. The capacity required for this one operation is a 500-kw station located near the center of the line. The reliability record of a modern rectifier station is 99+ per cent; however, sufficient stand by capacity must be available in case of a fault. Consequently, 1 1/2, 500-kw units are included. We can assume safely that one stand-by station could serve three similar lines. In actual practice where a large network is electrically connected together, this cost might be further reduced. Similarly, were this a single self-supporting line, two 500-kw stations would need to be installed, increasing the substation cost to $76,000.00.

You will note that the garage facilities for the trolley coach are considerably less than for the bus. This is justified for several reasons. Maintenance of trolley coaches is a relatively small portion of their operating cost. The absence of an engine is a great factor in this cost reduction. Further, an average trolley coach is approximately 2,000 pounds heavier than a bus. This weight is in axles and construction in general, giving a sturdier and more dependable vehicle. These factors combine to require less maintenance work and hence less maintenance facilities. This is further borne out by the number of spare vehicles required for service as explained above.

For operation in colder climates, this differential is further increased. Trolley coaches can be stored out of doors with absolutely no serious effect on starting or performance. On the other hand, most properties arrange for heated storage facilities for busses to enable reasonable starting characteristics. In southern climates where this storage is not necessary, the investment for bus garage would be approximately $60,000.00 Therefore, to summarize the investment needed to put either type of vehicle in operation, trolley coaches can be put into service for an investment of $460,440, and busses can be put into the same service for an investment of $410,500.

Operating Costs

Now that we have our investment figures for the two proposed vehicles, there remains the comparison of actual operating cost versus income. Operating costs consist of two major items, namely, fixed charges and operating expenses. First, we will consider fixed charges.

Tables V and VI show the fixed charges for each of the proposed systems. Depreciation is figured by dividing the first cost by the number of years of expected life. You will note that the expected life of the trolley coach is 12 years, while the expected life of the mechanical bus is only 8 years. This is based on actual practice of the transit industry at large. The rate of depreciation varies from 12–8 to a 20–10 ratio. For example, Boston, Mass., and Baltimore, Md., depreciate trolley coaches in 12 years and busses in 8 years. Des Moines, Iowa, depreciates trolley coaches in 20 years and busses in 10 years. Cleveland, Ohio, depreciates trolley coaches in 15 years and busses in 10 years. Our choice of 12 years for trolley coaches and 8 years for busses is reasonable.

Table V. Trolley Coach Fixed Charges

Depreciation	
Coaches (12 years)	$21,750.00
Overhead (20 years)	4,450.00
Feeder (20 years)	720.00
Substations (20 years)	2,800.00
Garage (50 years)	800.00
Total	$30,5200.00
Interest (average two per cent per year)	9,2000.00
Total annual fixed charges	$39,720.00

Table VI. Bus Fixed Charges

Depreciation	
Busses (8 years)	$36,400.00
Garage and facilities (50 years)	1,200.00
Garage storage (50 years)	1,200.00
Total	$38,800.00
Interest (average two per cent per year)	8,200.00
Total annual fixed charges	$47,000.00

Table VII. Trolley Coach Operating Expenses

	Cents	Per Vehicle Mile
Maintenance expense		
Ways and structures	1.29	
Equipment	4.12	
Power	.09	
Total		5.50
Operating costs		
Power	4.17	
Conducting transportation (drivers, and so forth)	13.9	
General and miscellaneous (claims, general office, salaries, and expenses, and so forth)	5.2	
Traffic	.06	
Total		23.33
Total operating expense (Not including taxes)		28.83 cents per mile

Table VIII. Bus Operating Expenses

	Cents	Per Vehicle Mile
Maintenance expense		
Bodies and chassis	4.65	
Tires and tubes	1.1	
Miscellaneous	2.4	
Total		8.15
Operating costs		
Fuel and oil	5.0	
Conducting transportation (drivers, and so forth)	14.6	
General and miscellaneous (claims, general office, salaries, and expenses, and so forth)	5.2	
Traffic	.06	
Total		24.86
Total operating expense (Not including taxes)		33.01 cents per mile

The depreciation rate for the remainder of the electric equipment and garages needs little explanation except that they represent a fair cross section of the industry in general.

Interest is assumed at an average of two per cent per year of the original investment. Obviously the interest rate is larger; however, as the investment is depreciated the payment becomes considerably less, and consequently, this is a simple way of expressing an average interest charge.

Totaling the fixed charges, we find that the trolley coach operation will cost $39,720 per year against $47,000 per year for the busses in fixed charges. This means that in spite of the higher first cost, because of the longer life of the trolley coach they actually cost $7,280.00 less per year than do the busses in fixed charges.

The next step in total operating cost is the operating expense. This includes the actual day-by-day expenses such as maintenance, fuel, drivers, and so forth. Tables VII and VIII list these items for the trolley coach and bus, respectively. Again the trolley coach figures were obtained from the ATA bulletin and represent a fair average of 24 operating companies operating large trolley coaches. The maintenance cost for ways and structures is 1.29 cents per mile. This cost is considerably higher than one would expect for new overhead as used for this illustration. The figure, 1.29, undoubtedly includes repairs to converted street car overhead and general rehabilitation. New modern overhead would not exceed $0.75 mile maintenance; however, the published figure is used herein.

Bus expense data were obtained by averaging a number of bus operating reports. In comparing figures of this sort, care must be taken to obtain data pertaining to vehicles of the same seating capacity operating on lines of similar traffic density, (both passenger and other vehicles), and operating over streets of the same general width, profile, and state of repair. Each of these factors seriously affects both operating expenses and schedule speed ability. It is obviously unfair to compare a 44-passenger vehicle with 36-passenger vehicle. It is also obviously unfair to compare two vehicles of the same size, one operating in congested areas and the other operating over wide free streets with few stops.

The foregoing figures are comparable as they represent data taken from lines operated under similar conditions.

By comparing Tables VII and VIII we find that the trolley coach costs 28.83 cents per mile to operate excluding taxes, while the bus costs 33.01 cents per mile excluding taxes. Basically the difference is found in maintenance and operators' wages.

You will recall in the first part of this paper we included additional garage and maintenance facilities for the busses. These added facilities are justified by the above maintenance costs. Because of the simplicity of the electric drive, the more sturdy construction of the trolley coach itself, and, further, the absence of engine vibration affecting vehicles, bodies, and chassis, the maintenance costs are considerably less for the trolley coach than for the mechanical bus operating as outlined above.

Summarizing thus far, we find that to operate trolley coaches on this line we must make a considerably larger initial investment than is required for busses. For this larger investment we will receive greater revenue. We also find that because of the longer life of the trolley coaches, annual fixed charge cost for the trolley coach operation will be considerably less than that for the bus operation. Further, we find that the actual operating expenses for the trolley coaches will be considerably less per year than those for the busses.

Table IX. Trolley Coach Annual Statement

	Cents Per Mile		Annual
Passenger revenue		50.9	$390,000.00
Expenses			
Operating expenses	28.83		
Fixed charges	5.17		
Total	34.00	34.00	
Net revenue		16.90	
Taxes	8.09	8.09	
Operating expense	42.09		322,500.00
Operating income		8.81	$ 67,500.00
Per cent return on investment		14.6 per cent	

Table X. Bus Annual Statement

	Cents Per Mile		Annual
Passenger revenue		45.8	$351,000.00
Expenses			
Operating expenses	33.01		
Fixed charges	6.14		
Total	39.15	39.15	
Net revenue		6.65	
Taxes	3.20	3.20	
Operating expenses	42.35		325,500.00
Operating income		3.35	$ 25,500.00
Per cent return on investment		6.2 per cent	

Annual Statement

The final analysis for our economic study is the annual statement. In the annual statement, Tables IX and X, the operating income is balanced against the total operating costs. After deducting operating expenses, fixed charges and taxes, the trolley coach operation leaves an operating income of 8.81 cents per mile or $67,500.00 per year. Expressed as a per cent of the initial investment, this is a return of 14.60 per cent.

The bus annual statement indicates an operating income of 3.35 cents per mile or $25,500 per year which in turn represents a return of 6.2 per cent on the original investment.

It is interesting to note that the trolley coach net revenue before deducting taxes is approximately two and one-half times the corresponding bus figure. This is obviously because of a combination of higher income and less operating expense.

Taxes used in this analysis represent the total of vehicles, facilities, and revenue

taxes, the basic figure of 8.09 cents per mile for the trolley coach being obtained from the ATA bulletin. As there is no ready means of computing bus operation taxes, the ratio of taxes to net revenue was maintained in both annual reports; hence total bus taxes are reduced considerably as a result of a reduced net revenue.

Conclusion

In conclusion, to answer the question asked by the title of this paper, the trolley coaches not only can compete with the bus under the conditions where no overhead or substation equipment exists, but they offer the most economical and satisfactory service.

Discussion

L. W. Birch (Ohio Brass Company, Mansfield, Ohio): Following a hearing before the Public Utilities Commission of New Jersey in June 1938, concerning the possible fire hazard introduced by 2-wire trolley coach overhead systems, the commission's subsequent ruling was rendered negatively. The overhead wires were not considered a hazard. Testimony was given during this hearing that indicated aerial ladders could be raised along the route and that there would be no impediment to fire fighting. It was also stated by several witnesses from operating companies that only in very rare cases have wires been cut to facilitate fire fighting. The negative wire located on the building side is usually 13 feet from the curb line, thus providing 20 to 25 feet between this wire and the building walls.

Radar Technique in an Industrial Control

W. D. COCKRELL
MEMBER AIEE

FOR a long time, industrial electronic engineers and communication engineers have felt that their circuits and techniques had little in common, that the one dealt with low frequencies and high power, whereas the other dealt with high frequencies and often with signals of extremely small power. However, with the development of such special communication fields as radar and loran, it has been found that many new circuits have been adopted in the communication field which are also quite useful in the industrial field. Therefore, it is highly desirable that the progressive electronic engineer in either field keep close contact with developments in the other so that he may take advantage of those which he may use best. Circuits such as square-wave circuits, clippers, blocking timing, and counting circuits normally associated with radar have an equally important place in industrial electronic circuits. In fact, the circuit to be described was designed before the war and before the present radar circuits were made available to the industrial engineer.

Typical Industrial Application—Photoelectric Side-Register Control

In the paper and printing industry, on slitting and processing machines where an accurate alignment of a web or strip is required, it is very desirable that the strip be wound or unwound so that its edge or a line of printing on it shall follow an exact path. Such a machine is shown in Figure 1. The basic mechanical operation will be seen more clearly from the simplified sketch of Figure 2. A photoelectric scanning head, shown in the center above the strip, views the strip edge or a printed line. Any deviation from the correct path is signaled to the electronic control panel at the right to excite an amplidyne generator. The amplidyne drives a correcting motor which moves the feed roll sidewise to correct the position or register of the strip.

Photoelectric Scanning Method

The photoelectric means developed to accomplish this result operates as follows: Because the most sensitive phototubes change their characteristics slowly over a period of time, it is desirable to operate on a sudden change of light, rather than on a continuous amount of light. To obtain a sudden change of light reaching the phototube, as reflected from the printing or edge of web, an optical system is used. It consists of four lenses mounted on a disk which is turned by a synchronous motor. The image of a lamp filament is projected through the lens onto the paper, and as the lens moves this small spot of light describes a quarter circle. Figure 3 shows a typical unit with cover removed. As the rotor of the small synchronous motor turns in accord with the electric voltage wave form, the position of the spot at any instant is related directly to the instantaneous value of the voltage driving the motor. Therefore, as the spot sweeps past the change in color corresponding to the register point, the change of phototube signal may be matched in time with the instantaneous value of the a-c voltage. In this way, a corrective action may be set up if the register point is not in its correct

Figure 1. A side-register control installation

Paper 47-47, recommended by the AIEE committee on industrial control devices for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 13, 1946; made available for printing December 19, 1946.

W. D. Cockrell is in the industrial engineering division of General Electric Company, Schenectady, N. Y.

position. The photoelectric scanning head including the optical system and phototube is set up so that the correct register position corresponds approximately to the midpoint of the light arc.

The principle of determining accurately the arrival of an electric pulse is fundamental in radar. Although here such extreme accuracy is not needed, we must determine times before, as well as after, the reference instants.

The use of the rotating-lens optical system to operate a reversing motor on an on-off basis is not new, but the circuits developed to provide a signal proportional to the direction and amount of misregister do involve a number of radar-like circuit elements and should be of interest. A previous system provided only that if the light spot occurred earlier or later than a critical phase angle that the correcting motor would be driven in a forward or reverse direction. However, inherent hunting action caused an excessive wear on the correcting mechanism and was not completely satisfactory. A circuit was needed which could apply a correction nearly proportional to the distance away from register so that the corrective action might be smooth and the motor might remain at standstill when no correction was needed.

Circuit Requirements

As outlined briefly, we must compare

1. An amplified phototube signal which has a comparatively steep wave front at the instant the light spot crosses the edge of the material or the printed line which will be used for register. Because the width of the line is indeterminate, and the surface over which the light passes afterwards cannot be controlled, it is desired to eliminate the phototube signal for the rest of the cycle as soon as the register signal has been obtained.

2. The instantaneous value of the sine wave alternating voltage which is indicative of the position of the moving light spot.

Our first step is to change the phototube signal into a uniform pulse and to eliminate all of the undesirable signals which the phototube may pick up.

Input and Pulse-Forming Circuit

In order to transform the somewhat indefinite signals coming from the phototube amplifier into a consistent signal, our first step is to use them to trigger a square-wave or gate circuit. Referring to Figure 4, we see that the circuit consists of a twin triode tube *3V* with common cathode resistor *11R*, and with the grid of the second triode driven from the anode of the first by a voltage divider, *13R* and *14R*, to provide snap action from full current to cutoff whenever the first grid passes a critical voltage. Switches are provided in the phototube amplifier so that the triggering signal is always in a positive direction.

The small circles at the top of the figures enclose oscilloscope traces of typical wave forms at the points indicated.

The Circuit Action—The Signal Trips

Before the circuit is tripped, the first triode *3aV* is normally nonconducting while the second *3bV* is conducting with zero grid voltage. When a positive pulse is applied by the phototube amplifier to the grid of the first tube through the capacitor *4C*, the first tube *3aV* begins to conduct, its anode potential drops to that of the cathode, and the grid of the second tube, through the voltage divider *13R* and *14R*, is driven sharply negative cutting off the second triode. The cathodes fall in potential permitting full current to flow through the first triode *3aV*. This instant in the operating cycle is shown at point *A* in the oscillograph traces above the diagram.

The grid of tube *3bV* is driven well negative below the *3aV* grid return point, *40*, so that no further action of the phototube amplifier will be effective to cut off the first tube. If the signal from the phototube amplifier should go very negative as shown in the oscillograph trace, the rectifier element of *4aV* limits the voltage to nearly that of point *40* and prevents any further negative swing.

Thus, we have accomplished the first requirement of obtaining a definite signal from the phototube and preventing any further signals from causing operation. We have developed a triggered gate circuit with rectifier blocking of reverse action.

Circuit Resetting Means

However, in order to make the circuit alive for the next cycle, we must reset it. This is done by means of an a-c voltage obtained from the transformer *2T* and the phase-shift circuit *13C* and *44R* which provides a sine wave of the proper magnitude and phase.

Rectifier *4bV* is so connected that during the positive part of this sine wave *4bV* is not conducting and the reset circuit is disconnected. However, as this reset voltage swings negative (as it does near the end of the light-beam sweep) *4bV* conducts and so makes the grid of *3aV* very negative. This stops *3aV* from conducting and resets the circuit. Furthermore, so long as the reset voltage is negative, *3aV* cannot conduct and signals from the phototube remain ineffective until the reset voltage again swings positive and releases the *3aV* grid. Point *B* on the oscillograph traces indicates the beginning of the reset time.

The Pulse or Pip Circuit

The signal which we wish to use as the indication of the instant of tripping is a

Figure 2. The fundamental parts of a side-register control system

Figure 3. A photoelectric scanner with rotating lens system

A (left). Unit with cover removed

B (right). Sketch of optical system

very sharp pulse of positive voltage. This is obtained by coupling a very small capacitor to the anode of the second tube *3bV* so that the output plate of the capacitor will be drawn quickly positive when the tube *3bV* stops conducting but will recharge rapidly to its original condition. The voltage appearing at the output of this portion of the circuit is shown in the right-hand oscillograph trace.

The output signal from this portion of the circuit consists of a single uniform pulse, accurately timed to the passage of the light spot past the paper edge or register line. This occurs once each electric cycle.

Error Detection Circuit

In this circuit (Figure 5), we compare the instant of passage of the light spot past the register line, as indicated by the uniform pulse which we have produced and the relative position of the light spot in its sweep, as determined by the instantaneous value of the voltage driving the synchronous motor. Because this voltage is a sine wave, which we may change in magnitude or reverse in phase easily by means of transformers, it provides a very desirable signal for our purpose. The relation between the voltage wave and light spot may be preset by the location of the lens disk on the motor shaft.

In practice, we confine ourselves to a 90-degree arc of movement. Because the scanner motor operates at 1,800 rpm, this allows 1/2 cycle (at 60 cycles) for operation. In a properly phased sine wave, the voltage swings from a positive maximum through zero to a negative maximum. If we apply this sine wave to the anode of a tube and use the pulse on the grid to permit conduction at the proper instant, we will release a brief surge or current corresponding to the instantaneous voltage applied. Thus, if we should phase our optical system so that the correct register point corresponds to the zero voltage of the sine wave, we can obtain a current flow proportional both to direction and distance from register.

Because an electronic tube is a rectifier and cannot pass current in both directions, we use two tubes: one which is supplied with voltage from one phase, and the other from the opposite phase of the

Figure 4 (left). Input and pulse-forming circuits

Figure 5 (right). Error-detection circuit, for polarity and magnitude

transformer. These are shown as *5aV* and *5bV* in Figure 5. If the positive pulses are applied to the grids of both tubes each cycle only that tube which responds to the direction of error will conduct current.

At this point, we have obtained a definite signal corresponding to the direction and amount of misregister, but it appears only as short pulse of current ineffective for operating a motor drive.

This circuit element employs a principle somewhat like that used to match a *PPI* sweep to the antenna position by energizing a selsyn with a pulse and obtaining an output pulse depending on the sine function of the rotor position.

The Pulse-Smoothing Circuit

In order to obtain a useful signal from the current pulses, they are used to charge two capacitors, *6C* and *7C*, of Figure 5.

The capacitor charges are drained off by shunt resistors, and as the current pulses arrive each cycle, each capacitor assumes a fairly constant voltage proportional to the charge received. The output from this part of the circuit is taken from the positive plates of the capacitors. The voltage between these leads is a comparatively smooth direct voltage indicating both by magnitude and polarity the amount of misregister.

The oscilloscope traces and voltmeters at the right in Figure 5 indicate three possible actions of this circuit. At the top, *X*, the pip has occurred before the zero point of the a-c cycle so that the left-hand tube *5aV* has conducted, charging *6C*. We will assume that the pointer of a zero-center voltmeter applied across the output leads would swing to the left.

For condition *Y*, the register is correct. The pip cuts the a-c wave at the zero-voltage point, and small equal charges appear on both *6C* and *7C*. The voltmeter indicates zero.

Finally, at *Z* the pip occurs late. Tube *5bV* charges *7C* and the voltmeter pointer swings to the right.

Output and Power Circuit

Once the misregister has been converted into a direct voltage, several means are available to provide power for the correcting motor. These include power electronic circuits, electromagnetic means, and the usual rotating exciters, and d-c generators. In this particular application, we will assume a fast-response generator, requiring low excitation power, known as the amplidyne.

The two balanced control fields which excite the amplidyne are supplied by a pair of output pentode tubes. These, in turn, are fed by a balanced voltage amplifier whose grids are responsive to the capacitor potential indicating the misregister. This voltage-amplifier stage consists of a balanced cathode-follower circuit sometimes given the descriptive name long-tailed pair. This circuit is coming into widespread use to provide symmetrical deflection for the plates of the cathode-ray-oscilloscope tube employed in radar, television, and many other fields.

Circuit Refinement

In an article devoted to the fundamental features of a circuit it is always desirable to eliminate those subordinate circuits which, while necessary in a practical design, tend to confuse a newcomer who wishes to trace the fundamental circuits. In the commercial equipment, there are rectifiers to supply direct voltage and filters for obtaining good wave form. Stabilizing or anti-hunt circuits are provided to obtain fast response with maximum circuit stability. Motor switches and protection are needed as well as push-button stations to permit manual operation of the correcting motor while setting up the equipment.

Figure 6. Output circuits and mechanical system

Conclusion

In this description of a typical industrial electronic application, we have tried to show that the elementary electronic tube circuits familiar to the radar man are not limited to one field only, but can be combined and arranged to serve many functional requirements. In industrial electronics, as in other fields, we obtain the most satisfactory results by breaking the problem down to its basic functions so that each tube circuit has but one job to do. These basic elements then may be combined to obtain the final results. Often in adding together the components, we are able to combine one or more functions without loss of operating efficiency. However, this can be done safely only if the essential functions for each circuit are kept clearly in mind.

No Discussion

A Balanced Amplifier Using Biased Saturable Core Reactors

H. S. KIRSCHBAUM
ASSOCIATE AIEE

E. L. HARDER
MEMBER AIEE

THE balanced amplifier using biased saturable core reactors was developed in the course of development of an impedance type regulator. Vacuum tubes were excluded from the latter device because of shock involved in the particular application, and it was essential that the amplifier also be nonelectronic. However, in addition to its shockproof characteristics, the resulting amplifier has unlimited life and a number of other features which suggest its use for a variety of other applications. It therefore was felt desirable to present the engineering features of this amplifier to the Institute.

The amplifier was required to amplify a small d-c signal of the order of 0 to 0.0004 watt to approximately 100 times this value. It also should handle 10 to 100 times this power with about the same amplification. It should be duodirectional, reversing the output for a reversal of input. The time delay was required to be not greater than two cycles (60-cycle basis) for certain applications but was permitted to be as great as one second in others.

A study first was made of the conventional saturable core reactor in a miniature size and it was found that 0.0004 watt was insufficient d-c excitation on the d-c leg of the reactor to produce enough flux density to have any material effect on the a-c legs.

Figure 1 shows the characteristic of a typical saturable core reactor. When used in the circuit shown, the power amplification is of the order of 20 to 40 times greater in region 2 of moderate d-c excitation than in region 1 of low d-c excitation.

The possibility of biasing the reactor to operate in the high amplification region was considered. However, with the extremely small signal power of 0 to 0.0004 watt superposed on the comparatively large bias power of a few watts, the signal of course, would be indistinguishable from small variations of the bias power supply. Bias by permanent magnet provided some interesting possibilities. However, the real answer to the problem was found in the form of a balanced amplifier design.

Balanced Amplifier

The amplifying element of the amplifier circuit consists of a 3-legged reactor as described by Aggers and Pakala.[1] This reactor is illustrated in Figure 2(*a*) and consists of a 3-legged core with one coil on each of the outer legs and two (or more) coils on the inside leg. The reactor coils (those on the outside legs) are connected so that the a-c flux Φ_A passes around the outside iron path as shown in Figure 2(*a*). None of this flux enters the center leg. The coils on the center leg carry direct current which sets up a flux Φ_D, which has a path through both outside legs thus permitting control of the degree of saturation of the iron of the a-c flux path. By controlling the saturation of the core, the permeability of the iron, and, as a consequence, the reactance of the reactor are under control. By varying the ampere turns on the center leg, the reactance of the reactor can be varied over a 30- or 40-to-1 range. The foregoing description is qualitative to the extent that the a-c and d-c magnetomotive forces are not superposable. Figure 2(*b*) illustrates the schematic equivalent circuit of the saturable core reactor, and it will be used to represent the reactor in the work which follows.

If the reactor is connected to a sine-wave voltage source as shown in Figure 3, and the alternating voltage across the reactor and the d-c amperes in one of the coils on the center leg are varied over wide limits, a family of curves as shown in Figure 4 will be obtained. The reactor current I_A will contain odd harmonics because of the saturation of the iron core. However, there will be no even harmonics because of the parallel connection of the a-c coils. The harmonic content will depend upon the extent of a-c and d-c saturations in the core.

The push-pull arrangement which is to be analyzed is illustrated in Figure 5. This amplifier consists of two biased saturable core reactors supplied by a 3-winding transformer which is used to isolate the reactor circuits. The bias is introduced in order to have an initial d-c saturation of the core, this being necessary for the successful operation of a push-pull amplifier and to obtain high amplification of small signals. The reactor currents are rectified before being passed through the load resistance, and, as a consequence, the abscissa and ordinates of Figure 4 are expressed in average instead of effective quantities. The rectified current of one of the reactors is passed through half the load resistance, and the rectified current of the other reactor is passed through the other half of the load resistance in such a way that the net voltage across the resistance is zero, when the control current I_C is zero.

As there is inherent unbalance in the amplifier, caused by slight differences in the reactors and so forth, initial balancing action is obtained by means of the resistor R_D. This refinement may be dispensed with where the amplifier output is not required to be zero at zero input.

When current is passed through the

Paper 47-48, recommended by the AIEE committee on industrial control devices for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 6, 1946; made available for printing January 6, 1947.

H. S. KIRSCHBAUM, formerly with Westinghouse Electric Corporation, East Pittsburgh, Pa., is now with Research Foundation, Ohio State University, Columbus, Ohio. E. L. HARDER is with Westinghouse Electric Corporation, East Pittsburgh, Pa.

The major portion of this paper is abstracted from a thesis, "A Static Power Amplifier Employing Saturable Reactors" by H. S. Kirschbaum, submitted to the University of Pittsburgh in partial fulfilment of the requirements for the degree of master of science.

Figure 1. Characteristics of a typical saturable core reactor

Slope 2 = 6.5 × slope 1
Power amplification in region 2 is $(6.5)^2 = 42$ times that in region 1

Figure 2 (right). Saturable reactor

Figure 3 (below). Test circuit for determination of reactor characteristics

control coil circuit, the bias ampere turns on one reactor are aided by the control coil ampere turns, and those on the other reactor are bucked by the control coil ampere turns. Thus one of the reactances decreases and the other increases. This unbalance in reactance causes a net voltage to appear across the load resistance. Because this load resistance generally will be a coil, the net average ampere turns of which will perform some useful function, the useful power input to the coil will be $V_R^2/2R$.

This device is a true d-c amplifier having no lower frequency limit and yet having complete isolation of output and input circuits, a feature much sought after in certain electronic amplifiers. It, of course, does have limitations for signals of more than a few cycles per second, as will be outlined later.

In Appendix I, the amplification of the amplifier is determined analytically in terms of constants of the reactor obtained from the characteristic curves shown in Figure 4. The voltage across the total load resistor $2R$ as a function of the control current I_C is

$$V_R = 2R\left[\frac{N_C X_O Z_{MO}}{N_B(R^2 + X_O X_{DO})}\right] I_C \tag{1}$$

and the power amplification is

$$A = \frac{R}{R_C}\left[\frac{N_C X_O Z_{MO}}{N_B(R^2 + X_O X_{DO})}\right]^2 \tag{2}$$

The symbols used are defined in Appendix IV.

From equation 2 it is obvious that if R were either zero or infinite, the amplification of the amplifier would be zero. There must be some value of R between zero and infinity which will give the maximum amplification. This optimum resistance is found by differentiating equation 2 with respect to R and setting the differential equal to zero. Solving for R yields

$$R_{opt.} = \sqrt{\frac{X_O X_{DO}}{3}} \tag{3}$$

It is a well-known characteristic of saturable core reactor amplifiers that if the d-c excitation is low, the center core is unsaturated and the time constant is long. The bias windings, therefore, not only greatly increase the amplification, but also reduce time constant, or increase the speed of action. Of course, a limit is reached, above region 2 in Figure 1, where a further increase in bias would improve the speed only at the expense of a decrease in amplification.

The time constant of the d-c input control circuit is the principal time delay involved in the device. Note that net coupling with the bias winding is substantially zero because of the equal and opposite coupling on the two cores. The time constant of the amplifier can be reduced by inclusion of resistance in the input circuit at the expense of reduction of over-all gain. In Appendix II, the following equation is developed for the time constant of the control circuit:

$$T_C = \frac{4X_O}{2\pi f R_C}\left[\frac{N_C}{N_A}\right]^2 \tag{4}$$

By the addition of another coil on the center leg of the reactor, positive (or negative) feedback can be introduced as shown in Figure 6. The output voltage sends a current I_F through the feed-back coils on the center leg in a direction to aid the control coil. Thus the amplifier will supply a portion of the energy necessary to sustain its output. This connection is stable up to the point where the amplifier supplies 100 per cent of this energy. Negative feedback can be secured by reversing the connections at the feed-back input as shown by the dotted lines in Figure 6.

The power amplification and time constant with feedback as developed in Appendix III are

$$A = \frac{A_O}{\left[1 \pm \frac{KN_F}{2R_F N_C}\right]^2} \tag{5}$$

$$T = \frac{\left[1 + \frac{R_C N_F^2}{R_F N_C^2}\right]}{\left[1 \pm \frac{KN_F}{2R_F N_C}\right]} T_{CO} \tag{6}$$

where

A_O and T_{CO} are the amplification and time constant without feed-back

R_F and N_F are the resistance and turns of the feed-back coil per reactor

$$K = \frac{2RN_C X_O Z_{MO}}{N_B(R^2 + X_O X_{DO})} \tag{7}$$

Table I. Amplifier Power Amplification

Method	Power Amplification
Calculated (equation 2)	187
Test (without filters)	169
Test (with filters)	266

For positive feedback the negative sign is used in equations 5 and 6, and the positive sign for negative feedback. The use of feedback permits wide control of the amplification and time constant of the amplifier. However, it must be borne in mind that the use of positive feedback gives greater amplification with the sacrifice of greater time constant and negative feedback gives a smaller time constant with a smaller amplification.

Experimental Confirmation of Analytical Results

Two reactors as described in the preceding section were built and tested to check the foregoing analysis. Illustrated in Figure 7 are the reactor core and coil data, the coils being wound as shown in Figure 2(*a*). The resistance of each a-c coil is 6.0 ohms, or 3 ohms for both coils in parallel, which is negligible when compared with the load resistance generally used with these reactors. Because the two reactors are duplicates, only one of them was tested in accordance with Figure 3. The current I_A was measured with a rectifier type ammeter, the current being expressed in average amperes, whereas the voltage V_X was measured with an iron vane type of voltmeter, the average voltage being determined by dividing the measured voltage by 1.11. The reactor characteristics as obtained are plotted in Figure 8. These data cover a range of reactance of over 30 to 1.

Using the two reactors, the circuit of Figure 5 was tested with the reactors operating initially at the point marked 0 in Figure 8. The voltage across the 210-ohm load resistance is plotted, as curve *A* in Figure 9, as a function of the control coil current I_C. The calculated curve, using equation 1, agrees within five per cent of the test up to a load voltage of 35 volts. At this point, the reactors cease to operate on the straight line portions of their characteristics, and the output voltage is no longer a linear function of the input current. The theoretical curve is above the test curve because of the resistance of the a-c coils and the selenium rectifier and also because of the leakage reactance of the transformer. These tend to reduce $\Delta I_A/I_C$ at the operating point.

By placing second and fourth harmonic filters across the total load resistance, as shown in Figure 5, the load voltage can be increased by approximately 25.5 per cent with a consequent increase of 58 per cent in power amplification. Table I lists the power amplifications on the linear portions of curves *A*, *B*, and *C* of Figure 9.

The amplifier circuit with the filters is not amenable to analysis; however, experience has shown that a gain of roughly 50 per cent can be expected in power amplification when they are used.

The reactors were operated at the point $V_{XO}=71.0$ volts, $I_{AO}=0.338$ ampere, $I_{BO}=50$ milliamperes, and the load resistance varied. Figure 10 illustrates the variation in amplification with load resistance, the optimum resistance being 230 ohms. At the point of operation, X_O is 210 ohms and X_{DO} is 360 ohms, which give an optimum resistance by equation 3 of 160 ohms. From the results of this test, equation 3 should be rewritten

$$R_{opt.}=0.76\sqrt{X_O X_{DO}}$$

This discrepancy between theory and test is not important because, near the peak of the amplification curve, it takes a wide variation in resistance to cause an appreciable change in amplification. The difference in amplification between the true optimum and calculated optimum resistances is only nine per cent.

Figure 11 illustrates the response of the amplifier to a suddenly applied direct voltage at the input terminals (for three different operating points) plotted as a deviation of output voltage from the ultimate output voltage on semi-log paper.

Figure 4. Reactor characteristics

Figure 5 (below). Amplifier circuit

From these curves, the amplifier time constants can be obtained. There is a slight subtransient effect at the beginning of the transient which probably is caused by eddy currents set up in the core of the reactor. The time constants so obtained are plotted in Figure 12 as a function of X_0. There is good agreement between test and theory, the maximum deviation being about 15 per cent.

Conclusions

The performance of the typical amplifier described may be summarized as an amplification of 150 to 250 for input signals as low as 0 to 0.0004 watts, with a time constant of 60 to 90 cycles. The amplification and time constant can be reduced proportionately by introduction of resistance; for example, to 15 to 25 with a 6- to 9-cycle time constant. Other sizes are, of course, feasible. By using two or more stages the over-all time delay can be reduced without reducing the power amplification.

The amplifier described should find its principle field of application where one or more of the following features are needed, and where the time delay involved can be tolerated:

1. True d-c amplifier, with no lower frequency limitations.
2. Complete conductive isolation of input and output circuits.
3. Operation to low input signals 0 to 0.0004 watt.
4. Amplification almost independent of variation of a-c supply.
5. Amplification almost independent of variation of bias supply.
6. Shockproof.
7. Unlimited life, no vacuum tubes.

A possible application is the regulating circuit shown in Figure 13. In this application the output of an impedance type regulator of low output is amplified to supply the field of a main exciter Rotorol. This requires reduction of amplification to improve the time constant. In another system, quick compounding is used to provide the major correction and slow accurate follow-up uses the full available amplification of the saturable core amplifier. The authors believe, however, that there are numerous other applications where the characteristics enumerated will be of value.

Figure 6. Feed-back amplifier

Appendix I. Amplification

In Figure 5 the total voltage at the secondary winding of the power supply transformer divides between the saturable reactor and the load resistor R. This voltage E will be assumed to remain constant for small variations of the current I_A.

Referring to Figure 14, the (average) voltage vector diagram of the circuit, the following equation can be written:

$$I_A^2R^2+V_X^2=E^2 \tag{8}$$

which when differentiated with respect to I_A gives

$$2I_AR^2+2V_X\frac{dV_X}{dI_A}=0 \tag{9}$$

Rearranging,

$$\frac{dV_X}{dI_A}=-\frac{R^2}{(V_X/I_A)} \tag{10}$$

Referring to Figure 4, the characteristic curves of the reactor, the initial operating point (no signal input to the control winding) is indicated by the point 0. Using the subscript 0 for all reactor quantities at this point, equation 10 can be rewritten

$$\left[\frac{dV_X}{dI_A}\right]_0=-\frac{R^2}{X_0} \tag{11}$$

Figure 7. Core and coil data of reactor

N_A—366 turns per coil
N_B—1,200 turns (150 ohms) per coil
N_C—3,200 turns (79 ohms) per coil

Figure 8 (right). Reactor characteristics

where

$$X_O = \frac{V_{XO}}{I_{AO}} \tag{12}$$

The expression for a small deviation in the voltage across the reactor can be derived from equation 11. It is

$$\Delta V_X = \left[\frac{dV_X}{dI_A}\right]_O \times \Delta I_A = -\frac{R^2}{X_O} \times \Delta I_A \tag{13}$$

The center-leg excitation of the reactor is contributed by two windings, the bias winding which contributes I_{BO} and the control winding which contributes ΔI_B. Because, in general, the control coil turns will not equal the bias coil turns,

$$\Delta I_B = \frac{N_C}{N_B} I_C \tag{14}$$

where

N_C are the control coil turns
N_B are the bias coil turns

Over a considerable portion of the family of curves of Figure 4, the curves are very nearly parallel straight lines, and they can be represented by the following equations:

$$I_A = I_{AO} + \Delta I_A$$
$$I_B = I_{BO} + \Delta I_B \tag{15}$$

$$V_X = V_{XO} + \Delta V_X$$
$$\Delta I_A = \frac{\Delta V_X + Z_{MO} \times \Delta I_B}{X_{DO}} \tag{16}$$

where

$$Z_{MO} = -\left[\frac{\partial V_X}{\partial I_B}\right]_{I_A = I_{AO}} \tag{17}$$

$$X_{DO} = \left[\frac{\partial V_X}{\partial I_A}\right]_{I_B = I_{BO}} \tag{18}$$

Equation 16 is the equation of a family of parallel straight lines with the point I_{AO}, V_{XO} taken as the origin. Z_{MO} is called the mutual transimpedance of the reactor and

Figure 9. Amplifier output versus input

X_{DO} is the dynamic reactance of the reactor at the operating point. Substituting equations 13 and 14 into equation 16, and solving for the ratio of ΔI_A to I_C at the operating point yields

$$\left[\frac{\Delta I_A}{I_C}\right]_O = \frac{N_C X_O Z_{MO}}{N_B(R^2 + X_O X_{DO})} \tag{19}$$

From equation 19, the power amplification A can be derived as follows:

$$A = \frac{2R}{2R_C}\left[\frac{\Delta I_A}{I_C}\right]_O^2 = \frac{R}{R_C}\left[\frac{N_C X_O Z_{MO}}{N_B(R^2 + X_O X_{DO})}\right]^2 \tag{20}$$

where

R_C is the control coil resistance of one reactor.

Equation 19 also may be used to find the voltage across the total load resistance:

$$V_R = 2R \times \Delta I_A = 2R\left[\frac{N_C X_O Z_{MO}}{N_B(R^2 + X_O X_{DO})}\right] I_C \tag{21}$$

Appendix II. Time Delay

Because the control coil circuit of the amplifier has inductance, the control coil current will lag behind the signal voltage applied to the input terminals. The amount of this lag is the time constant of the amplifier and is the ratio of the control coil inductance to its resistance. The presence of both d-c and a-c fluxes in the core of the reactor makes the calculation of the d-c flux extremely tedious.[3] However, an approximate method for calculating the inductance of the control coil can be developed by determining the average permeance of the iron path which is traversed by the a-c flux. The average reactance of the reactor is a measure of this permeance. Solving for this permeance,

$$P_O = \frac{X_O}{2\pi f N_A^2} \tag{22}$$

where

P_O is the average permeance of the a-c flux path
N_A are the reactor turns effective throughout the path

In saturable reactors of normal proportions, the physical length of the a-c flux path is very close to 1.5 times the length of the d-c flux path. In addition, the cross-sectional area through which the d-c flux passes is twice that through which the a-c flux passes. However, the permeance of the center leg is higher (because of lower average flux density in this leg) than that of the remainder of the core. If the permeance of the center leg were very much greater, the average permeance of the d-c flux path would be $4P_O$:

$$P_C = 4P_O = \frac{4X_O}{2\pi f N_A^2} \tag{23}$$

where

P_C is the average permeance of the d-c flux path

Figure 10 (left). Power amplification versus load resistance

Figure 11. Load voltage versus time for suddenly applied signal

Figure 12 (left). Time constant versus X_O

Figure 13. Generator voltage regulating system having low power measuring circuit and one or more stages of balanced amplification using biased saturable core reactors

From equation 23 the inductance of the control coil is

$$L_C = N_C^2 P_C = \frac{4X_O}{2\pi f}\left[\frac{N_C}{N_A}\right]^2 \tag{24}$$

And the time constant of the control coil is

$$T_C = \frac{L_C}{R_C} = \frac{4X_O}{2\pi f R_C}\left[\frac{N_C}{N_A}\right]^2 \tag{25}$$

The coupling of the control coil with the bias coil in one reactor is cancelled out by the coupling in the other reactor, because the control coils are wound in aid of the bias coil on one reactor and in opposition on the other.

Appendix III. Feedback

From Figure 6, which shows the equivalent circuit of the amplifier with positive feedback, the power amplification and time constant can be determined by solving for the output voltage of the amplifier as an operational function of the input voltage.

The voltage equations in the control and feed-back circuits for a suddenly applied voltage V_C are

$$V_C = 2R_C I_C + 2L_C p I_C + 2Mp I_F \tag{26}$$

$$V_R = 2R_F I_F + 2L_F p I_F + 2Mp I_C \tag{27}$$

where

$p = d/dt$

From equation 1,

$$V_R = \frac{2RN_C X_O Z_{MO}}{N_B(R^2 + X_O X_{DO})}\left[I_C + \frac{N_F}{N_C} I_F\right] \tag{28}$$

Letting

$$\frac{2RN_C X_O Z_{MO}}{N_B(R^2 + X_O X_{DO})} = K \tag{29}$$

$$V_R = K\left[I_C + \frac{N_F}{N_C} I_F\right] \tag{30}$$

Assuming 100 per cent coupling between the control and feed-back coils,

$$L_F = \left[\frac{N_F}{N_C}\right]^2 L_C \tag{31}$$

$$M = \frac{N_F}{N_C} L_C \tag{32}$$

Equations 26 and 27 now can be rewritten by substituting equations 30, 31, and 32 into them.

$$V_C = 2R_C I_C + \frac{2L_C}{K} p V_R \tag{33}$$

$$V_R = 2R_F I_F + \frac{2N_F L_C}{KN_C} p V_R \tag{34}$$

The currents I_C and I_F can be eliminated between equations 33 and 34 with the aid of equation 30. Solving for V_R,

$$V_R = \frac{K/2R_C}{\left\{\left[1 - \frac{KN_F}{2R_F N_C}\right] + T_{CO}\left[1 + \frac{R_C N_F^2}{R_F N_C^2}\right] p\right\}} V_C \tag{35}$$

where

$T_{CO} = \frac{L_C}{R_C}$, the control coil time constant without feedback

The power amplification can be found from equation 35 by setting p equal to zero and solving for the ratio of power output to power input

$$A = \left[\frac{V_R}{V_C}\right]^2 \frac{2R_C}{2R} = \frac{A_O}{\left[1 - \frac{KN_F}{2R_F N_C}\right]^2} \tag{36}$$

where

$A_O = \frac{K^2}{4RR_C}$, the power amplification without feedback

$$T_C = \frac{\left[1 + \frac{R_C N_F^2}{R_F N_C^2}\right]}{\left[1 - \frac{KN_F}{2R_F N_C}\right]} T_{CO} \tag{37}$$

In a similar manner the amplification and time constant with negative feedback can be developed. They will differ from equations 36 and 37 only in that the negative sign in the denominators of these equations will be positive.

Figure 14. Vector diagram of amplifier circuit

All voltages and currents are average

Appendix IV. Nomenclature

N = turns
I = current
V = voltage
E = supply transformer secondary voltage
X = reactance
R = resistance (when used without subscript it is the load resistance)
Z_M = mutual transimpedance of the reactor
X_D = dynamic reactance of the reactor
A = power amplification

Subscripts have the following significance:

O = at the operating point
C = control coil
X = reactor a-c coil
F = feedback
A = reactor a-c and load circuit
B = bias oil
R = load resistor

Burning of Wood Structures by Leakage Currents

PAUL M. ROSS
MEMBER AIEE

Synopsis: Wood pole or structure fires of leakage-current origin have caused serious wood-member damage and service interruption. These fires often occur at the end of prolonged dry periods. Operating experience indicates surface tree carbonization on crossarms and pocket burning at the crossarm-pole junction to be the two general types of burn damage. Pocket burning on some properties has been responsible for the larger part of the cases that required wood-member replacement. Laboratory tests conducted on approximately 200 specimens indicate that a coincident occurrence of dry wood and selective wetting of pole and crossarm surfaces by a light rain or fog, wind directed, which leaves a dry wood area in series with the leakage path, can result in a fire of a pocket type. This dry area, being high in resistance in comparison with adjacent series wetted-wood surfaces, results in a voltage concentration across the dry zone. If the dry zone is sufficiently short for a given circuit voltage, electrical breakdown occurs across the dry zone. This electrical breakdown being located favorably in dry wood and encouraged by a breeze may result in a pocket burn. Shunting devices which by-pass leakage currents around dry high resistance areas have proven successful in laboratory tests in eliminating pocket fires within the by-passed zone.

PRACTICAL and prime objectives in the operation of power lines are continuity of service and the prolonged life of physical equipment. One of the several causes that may prevent the realization of these objectives is the burning of wood structures by leakage currents. Because the majority of the medium voltage lines on this continent are constructed on wood poles, this constitutes a considerable problem.

Pole or structure fires may be caused by power-frequency leakage currents which flow over the surface of contaminated insulators and through supporting wood members. In some localities these fires may occur at infrequent intervals and are only an incidental nuisance. In others they may occur frequently and may be of such a character as to result in the complete loss of the crossarm and pole and cause a prolonged service outage.

Field Operating Conditions

Pole fires usually are preceded by three general conditions.

1. They are preceded by a prolonged dry period in which the wood members dry out.
2. During this dry period contamination accumulates on the insulator surface. The accumulated contamination layer reduces the surface leakage resistance of the insulator, particularly when it becomes dampened. The contamination may be salt deposits in coastal areas, dust on the plains, or smoke and other air-borne by-products from industrial establishments.
3. The dry period is followed by a fog, misty rain, or even snow.

Any fires that result may become evident shortly after precipitation has occurred, or they may not break out into the open until a later time or even until after precipitation has stopped.

Figure 1 shows carbonized surface burns on crossarms which were caused by leakage currents. The tree-like appearance of the burn patterns suggests that this be called tree burning. This type of burning is quite common. It usually does not result in burn damage sufficiently extensive to require replacement of the wood members.

Figure 2 illustrates burn damage on a pole and on a crossarm, which occurred at the gain areas. The burns are pocket-shaped and extend into the body of the members; they are not confined primarily to the surface as are tree burns. The

Paper 47-49, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted November 13, 1946; made available for printing December 5, 1946.

PAUL M. ROSS is superintendent of the high-voltage laboratory of the Ohio Brass Company, Barberton, Ohio.

Figure 3. A schematic circuit diagram illustrating the series-circuit relation of insulator-surface leakage resistance with supporting wood members

burn damage in these cases occurred predominately on one side of the through-bolt. Pocket burning does not occur as often as tree burning, but when it does it is more likely to result in the need for replacement of the wood members. One property has estimated that approximately three-fourths of their cases of burn damage which required wood member replacement have been of the pocket-burn type. The specimens in Figures 1 and 2 were removed from service installations.

The foregoing are the general conditions that are the setting for wood burning of leakage current origin. The number of pole fires is small relative to the total number of circuit-pole-years of operation. This suggests that because the probability of a fire is small, a coincidence of unfavorable conditions is required to produce the event. Therefore, there is a need for finding the combination of conditions which may result in a fire.

Laboratory Approach to the Problem of Pocket Burning

The magnitude of leakage currents that flow through a porcelain-wood combination is controlled principally by the total resistance of the wood plus the surface leakage resistance of the insulator. It is controlled largely under the lesser contamination conditions by the insulator. The insulator and the supporting wood members therefore comprise a series circuit. This is illustrated in Figure 3. Any leakage current that might flow from phase *A* conductor to ground, for example, must flow through the surface leakage resistance of the insulator and then through the crossarm and pole resistance.

Leakage currents have been found by measurement to be surges.[1] Magnetic oscillogram records of leakage current surges taken in our laboratory show that the surges vary in magnitude of maximum current, frequency of occurrence, and time duration of individual surges. This investigation was started by the use of surges that were controlled in these three variables. It was found that the burn damage obtained with these surges could be duplicated in a shorter time by the use of a continuous-power frequency leakage current. Therefore, for the purpose of speeding up the investigation, a constant leakage alternating current of ten milliamperes was used. This is a typical value that may be expected in service.

In order to cause the leakage current to be controlled principally by a circuit element other than that of the wood resistance (thereby simulating the presence of an insulator with a constant leakage resistance) an impedance was inserted in series between the test transformer and the wood specimen. This test arrangement is shown in Figure 4. With the wood specimen in Figure 4 jumpered out, the test transformer voltage was adjusted so as to cause ten milliamperes to flow through the series impedance. It was found when the jumper was removed and the previously established transformer voltage reapplied that if the wood specimens were dry, the wood resistance was exceedingly high[2] and by itself limited the current through the series circuit to values less than one-half milliampere. If only one longitudinal surface of the same wood specimen were dampened the leakage current through the circuit would rise immediately to approximately ten milliamperes, thereby indicating the wood resistance had decreased through a wide range.

Figure 5 illustrates the nature of the influence of moisture content on the electrical resistance of wood. These data were obtained from reference 3 which states, "A surface film of moisture caused by condensation or rainfall will lower the resistance of the surface of a dry piece to that of a piece with a moisture content of 25 per cent or more." The ordinates in Figure 5 are relative resistance ratios based on the resistance at 25 per cent moisture content as unity. Depending upon the length of the drying period and the surrounding atmospheric conditions,

Figure 6. A schematic series-circuit diagram illustrating the reduction in surface resistance of dampened wood and the relative lack of reduction in dry shadow or gain area

the moisture content of the wood may reach values as low as ten per cent. If this were assumed to be the case, the wetting of one surface of a piece of wood would reduce that surface's resistance in the order of 1,200 or 1,400 to 1.

Figure 6 shows a portion of a wood structure consisting of a wood pole, a wood crossarm, and a porcelain pin type insulator mounted on a steel pin. The direction of a light wind is assumed relative to the structure. With this air movement direction the surfaces indicated by the cross marks will become dampened selectively. A schematic series circuit of this physical arrangement is shown to the right. The insulator surface leakage resistance is indicated between the conductor and the metal pin. That portion of the crossarm which is dampened is represented as a low resistance. Similarly, the dampened portion of the pole surface extending either to another phase or to ground is represented as a low resistance.

There remains, however, a connecting area between the end of the wetted portion of the crossarm surface, point *C*, and the nearest electrode which is the crossarm and pole through-bolt *D*. This area has not been dampened because of the particular air movement direction and therefore has a high resistance. This high resistance area consists of the pole shadow on the crossarm with respect to the air movement direction and the dry gain area between the crossarm and pole. The flow of leakage current through this series circuit causes a large *IR* voltage drop to appear across the dry high resistance area.

To verify, experimentally, the existence of a voltage concentration across the dry zone, equipotential lines in the electrostatic field surrounding a specimen were located and plotted. Figure 7 was obtained by these measurements. This is the top view of an untreated dry pine pole which was gained and fitted with a section of dry Douglas-fir crossarm. The flat steel plate was the voltage application electrode. Twelve kv was applied at this point. A circumferential copper braid band, located one foot below the through-bolt, was the ground electrode. The 25 per cent (3 kv), 50 per cent (6 kv), 75 per cent (9 kv) equipotential lines first were determined for the dry condition.

The same specimen then was wetted selectively as it might occur with the assumed air movement and moisture direction of Figure 6. The pole surface was dampened from the through-bolt to the ground band. About six inches of the face of the crossarm extending from the voltage application electrode was wetted. There remained the dry wind-shadow of the pole on the crossarm and the dry arm-to-pole-gain area. The equipotential line locations for this wetted condition are plotted in solid lines. A large change in the electrostatic field is indicated by comparing the dotted line map with the solid line map. The wetted pole surface being low in resistance has placed the through-bolt at near ground potential. In effect, the wetted crossarm surface has extended the voltage application electrode to the edge of the wetted area. As a result, a voltage concentration zone as shown in

Figure 7. The influence of dampened pole and crossarm surfaces in forming a voltage concentration zone at the gain

Figure 8. These selectively dampened pole and crossarm surfaces cause a voltage concentration to occur across the dry series zone

Figure 8 appears between the end of the wetted crossarm surface and the through-bolt.

Figure 9 shows the crossarm and pole arrangement used in the equipotential line-mapping tests. The pole surface and crossarm were wetted by a light finely divided mist applied from an air-operated spray gun. The wind direction was simulated by a fan. The front of the pole was dampened between the through-bolt and the grounded band, and it therefore had a low resistance. The arm also had been dampened from the steel electrode to the edge of the pole shadow. The pole shadow and gain were dry. As the light water spray was continued the dampened arm surface encroached on the pole shadow until an electrical breakdown took place between the nearest edge of the wetted surface and the through-bolt. The outer end of the breakdown path is indicated by arrow.

The crossarm was removed from the pole in Figure 10. A carbonized path was found to have developed from the through-bolt across the gain. The mating crossarm burn, indicated by arrow in Figure 11, extended from the through-bolt out to the wetted portion of the arm. Drying of the arm surface occurred at the outer end of the crossarm burn.

In Figure 12 the structure was reassembled and the test continued. The current flowing was ten milliamperes, 60 cycles per second, as controlled by the series impedance. Encouraged by the breeze, open flames appeared in about ten minutes.

Figure 13 was taken by looking along the crossarm toward the pole. A pocket was burning into the crossarm and into the pole at the original carbonized path locations. The fire continued without the help of leakage current at this stage.

Figure 14 shows the pocket burn that formed to the left of the through-bolt in the pole and to the right of the through-bolt hole in the crossarm. These pockets are similar in appearance and location to those found on the field burned specimens shown in Figure 2.

If the direction of the air movement is changed so that the crossarm and pole become dampened as shown in Figure 15, a voltage concentration zone occurs across the lower side of the crossarm and from the through-bolt toward the wetted pole surface below. A fire that resulted from these conditions is shown in Figure 16. Figure 17 shows the pocket burn damage that resulted on the crossarm and pole. This fire was initiated by a tree burn across the lower surface of the crossarm. The lower surface of the crossarm was turned upward in Figure 17, and part of the original tree burn indicated by arrows is still present.

Throughout these tests, weathered crossarm and pole sections were used. The large hole at the right end of the crossarm in Figure 17 was used previously for a wood pin when the arm was installed in service. The through-bolt hole used in these tests is indicated by asterisk.

The preceding examples of burn damage are typical of the many obtained during the investigation. Controlled leakage current surges produced the same type of damage.

Figure 9. Electrical breakdown took place between the through-bolt and the near edge of the wetted crossarm surface. This is the start of a pocket burn

Remedial Devices for Pocket Burning

Voltage concentration across high resistance sections may be avoided if a low resistance shunt is placed in parallel with them. Figures 18 through 21 show four

possible shunting arrangements. The assumed air movement direction and the resulting selective wetting are the same as in Figures 15 and 16. The shunting devices are also effective on other air movement directions such as Figures 8 and 9.

In Figure 18 leakage currents originating on the crossarm leave the wet and conducting surface at *A* and enter the circumferential arm band *B*, flow through crossarm jumper *C* to the through-bolt *D*, flow the length of the through-bolt and enter the pole jumper *E*, flow through pole jumper *E* to pole band *F*, then flow around pole band *F* to the wet and conducting pole surface at *G*. These interconnected bands thereby present a low resistance path which shunts the leakage currents past the dry high resistance shadow and gain area.

The completeness of the previous banding arrangement might be simplified as shown in Figures 19 through 21. These devices are connected to the through-bolt and extend beyond shadow areas onto the pole and crossarm.

Pocket burns have not occurred within the shunted area while using these de-

Figure 12 (left). Open flames appeared in about ten minutes

Figure 13 (right). A pocket burn developed on the pole and crossarm at the location of the original carbonized paths

Figure 15. This assumed wind and rain direction casts a relatively dry crossarm shadow on the pole. In addition to the shadow the gain is dry. A voltage concentration occurs across these dry zones

Figure 19. A metal gain-plate shunt

Figure 21. A preformed ring may be used as a shunt

vices during laboratory tests. To obtain this result it is necessary that the leakage current collecting edges of the devices be located outside of all wind shadows of either crossarm or pole and be terminated snugly against the wood's wetted surfaces.

Shunting devices possess certain disadvantages.

1. They may reduce in small degree the impulse insulation contributed by the wood structure.

2. The elimination of high resistance areas may tend to increase the magnitude of leakage current because this magnitude is controlled partially by the wood structure resistance.

3. If improperly designed and applied, the shunting devices may cause an aggravated tree-burning condition at the current collection edges of the shunting electrodes.

4. The shunts, being metallic, are subject to corrosion, and therefore the life of the device should be questioned in relation to the structure it is protecting.

Experience gained from actual installations will be required in order to evaluate the relative merits and demerits of these devices.

A second approach to the elimination of a voltage concentration zone is through the use of wood treatments which would increase dry wood conductivity. Various other forms of remedial devices undoubtedly will suggest themselves to the practical operator. The final forms will be dictated by cost and expected life.

Conclusions

1. Operating experience indicates the consequences of pocket burns to be more expensive than tree burns.

2. Laboratory tests indicate that a coincident occurrence of the following conditions may result in pocket burn.

(a). Dry low-conductivity wood.

(b). The selective wetting of the pole and crossarm surface by a precipitation which leaves dry high resistance zones in series with low resistance wet sections of the leakage path.

(c). A dry zone which is sufficiently short so that the circuit voltage will cause electrical breakdown to occur across it.

3. Laboratory tests show that metallic shunting devices which by-pass leakage currents around high resistance dry zones are effective in preventing pocket burns within the shunted zone.

4. The selection of a final form of remedial device will be dictated by the initial and installation cost of the device itself and its expected life in relation to the structure it is protecting.

Discussion

L. D. Cronin (Ebasco Services, Inc., New York, N. Y.): A short time ago I inspected several poles where burning by leakage currents has occurred and I can assure Ross that the types of wood burning which he has produced in the laboratory are very similar to those actually occurring in the field at least in so far as the pole is concerned. The arms had been replaced in the locations which I inspected. Ross has provided a very logical explanation of the occurrence of pocket burns at or near the junction of the pole and the crossarms. His paper represents a real contribution to the knowledge of the subject.

It would have been very helpful if the metal braces ordinarily used on distribution circuits had been included in the test setup so that their effect could have been determined. It may be noted that the braces provide a metallic path for the leakage current around the high resistance "shadow" area in the same manner as the shunting devices described in the paper. Perhaps the reason that the braces do not prevent burning in the shadow area is that there is insufficient contact area on the arms and on the pole at the end of the braces. The use of bands around the arm and around the pole at the ends of the braces and electrically connected thereto, might make it possible to accomplish the desired shunting of the danger area in a simpler and easier manner.

W. H. Wickham (Commonwealth Edison Company, Chicago, Ill.): Ross' paper suggests two points which merit further consideration.

1. The importance of the resistance of the junction between pole and crossarm in limiting the current in the porcelain–wood circuit.

2. The importance of selective wetting as a factor in producing burning of the wood members.

In selecting a value of series impedance to be used in the test circuit Ross has assumed that the resistance of the wet wood circuit is of no importance in controlling the leakage current and, with the test arrangement shown in Figure 4 of the paper, this is the case. However, for the test arrangement of Figure 9, this may not be the case. In fog or misty rain the gain surface on the pole and the surface of the crossarm in contact with the pole remain relatively dry. Furthermore, at this junction some of the current must take a path across the grain of the wood in passing from the crossarm to the pole. So, even though wetting reduces the resistance of the individual wood members to a low value, the resistance at the junction between the two may remain relatively high. These conditions would suggest that a much lower series impedance would more nearly represent field conditions and would change the behavior of the wood portion of the circuit.

The higher resistance of the wood circuit in the gain area gives the voltage concentration necessary to produce burning without selective wetting. This accounts for the occurrence of wood burning in fog conditions, with practically no wind, where selective wetting can hardly take place.

F. E. Andrews and **R. W. Caswell** (Public Service Company of Northern Illinois, Chicago, Ill.): The paper by Ross is a valuable contribution to the knowledge and information on a very troublesome operating problem which heretofore has had inadequate investigation as a general technical subject.

During the past ten years we have experienced about 60 cases of pole fires on 33-kv lines due to leakage currents under the field conditions referred to by Ross. About two-thirds of the cases occurred during 1944 and 1945. This concentration of troubles probably resulted from a combination of weather conditions especially conducive to creating the necessary leakage and an acceleration of dirt deposits under wartime industrial conditions. This illustrates the erratic expectancy of this type of trouble. Several years may pass with very little of it, to be followed by an epidemic within a few months to one or two years following.

In addition to the burning at junction of pole and crossarm, we have had vertical corner poles burned at the bolt used for attachment of the dead end insulators to the pole. Approximately one-third of our fires have been on vertical corner poles.

Our experience indicates that the use of more porcelain insulation than normal does not prevent pole fires. Fires have occurred on poles in 33-kv lines using 35-, 45-, and 55-kv pin-type insulators, and at strain insulator dead ends on vertical corner poles with widely varying amounts of insulation. This insulation has varied from a minimum of two $6^1/_2$-inch spaced units to a maximum of 5. Three units are normal either with $5^3/_4$- or $6^1/_2$-inch spacing. Fires due to leakage have occurred with both types of insulators.

Many of these fires have been in areas that are not considered as excessively dirty. We have not been able to determine that the presence or absence of creosote treatment of poles and arms has any important influence on their susceptibility to fires, as fires have occurred on both treated and untreated poles and arms.

We have found that the presence of a static wire ground lead on a pole does not prevent fires at junction of the arm and pole. In addition to burning at junction of pole and arm, we have experienced burning off of the crossarm about midway between the insulator and the pole.

During the past two years we have installed some band arrangements following the same principle as shown by the author's Figure 18. However, we wrapped the pole and arm with small soft drawn copper wire, usually Number 18. The small wire is used in preference to a strap because it is believed that the wire will provide a more intimate contact with the wood surface over a longer period of time than straps which may not so closely follow the contour of the wood surface. We have also used this wire method to connect the pole to the insulator hardware at vertical corners. So far we have had no fires on poles protected in this manner, but we consider that our operating experience is insufficient to assume that this remedial measure is fully effective.

Figure 1. Metal braces provide low resistance shunt paths for the current flow direction *A-B-C*, also *A-B-F-G*, but not *A-D-E*

H. E. Weaver (Public Service Company of Northern Illinois, Maywood, Ill.): Ross should be commended for his paper and this discussion is in the nature of a corroboration rather than a criticism of the paper.

Ross used ten milliamperes of leakage current in order to get results quickly, but, in independent laboratory studies that we have made, we got fires with eight milliamperes, found that with three milliamperes burning would continue slowly and quietly, and that with one milliampere of leakage current the carbon in the charred spots would continue to glow.

Apparently leakage currents of ten milliamperes frequently occur in practice. After periods of dry weather, the surface resistance of line (37 kv) insulators, when sprayed with distilled water, was found to be the order of 0.2 to 20 or more megohms with an appreciable percentage falling in the one half to one megohm class. The appearance of the insulators is often unreliable as a means of estimating its wet surface resistance.

For convenience, Ross used an imped-

ance, between the testing transformer and the wood circuit, to simulate an insulator. On some of our tests, we used a regular line insulator in series with the wood circuit. Burning could be established and maintained, after spraying water on insulators that had accumulated storeroom dust for a period of two months, and burning could easily be started when using insulators that had been removed from service near a chemical plant, even after they had been flushed off with water.

Of the methods of mitigating burning, which were mentioned in the paper, our tests tended to show that banding the pole and arm would be the most effective for it seemed easier to maintain good contact with the wet surfaces.

M. S. Oldacre (Commonwealth Edison Company, Chicago, Ill.): It is obvious to anyone who has seen the demonstration of the work described by Ross that a real contribution has been made to our knowledge of the pole burning problem. This discussion is to suggest some of the other phases of the problem that exist.

The insulator is a very important part of the leakage circuit under ordinary conditions, but under wood burning conditions seems to become a negligible factor. Thus there is a field for insulator development for specially contaminated areas. The requirements seem to be that a reasonable portion of the surface remains dry under all conditions or that there be enough leakage surface so that the current will be less than enough to cause burning.

It would seem that the surface conductivity of the pole and cross arm is of vastly more importance than the conductivity of the mass of the wood. That is, there should be no great difference in the burning characteristics of so-called dry or wet wood if the surface conditions were suitable to cause burning. If this statement is not correct, there would undoubtedly be many cases where the shunting devices across the joints would be ineffective. Actually the shunting devices perform as expected if their condition remains as good as when installed.

More knowledge is still needed on this subject and it is suggested that some of the factors to be considered are:

1. Effects of different surface treatments or impregnations of poles and arms.
2. Shunting devices of low cost and easy application that will remain effective during the life of the poles and arms.
3. Consideration of insulator design to secure an effective dry area under all conditions.
4. Selection of insulators that will give enough leakage surface to prevent burning under contaminated conditions. This would assume that insulators could be washed or otherwise cleaned prior to the period of the year when contamination is likely to contribute toward burning of the wood.
5. On double circuit lines the location of the corresponding phases of the two circuits should be selected to avoid concentration of leakage current at any one connection.

The ultimate solution to the problem may be a combination of results from the above items as the cost of making the changes must not be overlooked.

Paul M. Ross: The nature of the questions and character of the comments given by the various discussers of this paper indicate that they have given careful consideration to the various phases of the problem of pole and crossarm burning.

Cronin has requested an explanation of the shunting action afforded by metal braces. Figure 1 of the discussion presents a typical pole and arm construction including the use of metal braces. An air movement direction has been assumed which is parallel with the conductors. If the air movement carries with it a form of precipitation, the indicated areas of the structures will become dampened and these wetted wood portions will therefore have relatively low resistance. Assuming that leakage current flows from the right-hand insulator, it would flow in direction *A*, through the conducting surface of the wetted arm to the brace, then down the brace in direction *B* and leave the brace on the wetted and conducting pole surface in direction *C* in order to reach another phase or grounded point below.

If the leakage current path is from phase-to-phase between the right-hand insulator and the left-hand insulator, the leakage currents would flow from *A* down the brace in direction *B*, up the left-hand brace in direction *F* and through the wetted arm surface in direction *G* to the left-hand insulator. This latter path is in parallel with the low resistance wetted arm surface joining the two insulators. In these two cases the braces do provide a shunting action.

If, however, the leakage current flows between the right-hand insulator and either some other phase or a grounded point higher on the pole, the leakage current would flow in direction *A* and *D* through the wetted surface of the arm and then must leave the arm surface and flow thru the wet conducting surface of the pole *E*. Unless the arm fits snugly into the pole gain, a gap may exist between the top of the arm and the pole surface as shown in section *M-M*. If there is such a discontinuity in the wetted conducting surfaces between the arm and the pole, a voltage concentration zone will appear at that point and this zone is, therefore, a possible pocket burn location. The braces in this case do not provide a shunt for the leakage current around this voltage concentration zone because the wet surface of the pole above and below the arm is interrupted by the dry shadow of the arm and the gain.

In Figure 2 of the discussion, the assumed air-motion direction causes the pole structure to be wetted on the opposite surface from that in Figure 1. In this case the metal braces provide a shunt path by-passing the high resistance shadow zone between the arm and the pole for leakage currents flowing from the right-hand insulator to the left-hand insulator. The braces do not, however, provide a low resistance shunt if the leakage current flow is either to another

Figure 2. Metal braces do not provide a complete low resistance shunt path for either current flow directions *A-B-C-D* or *A-E-F-D*

Figure 3. Leakage current density is greatest at edges of metal parts. Drying proceeds faster in wood areas *A* adjacent to metal parts. Tree burning develops across *A*

Figure 4. Suggested method for reducing tree burning at metal attachment points

phase or to ground at a location above or below the crossarm.

There are two surface paths available by means of which the leakage current starting from the right-hand insulator in direction *A* may reach the wet conducting surface *D* of the pole. The current may flow downward through the metal brace in direction *B* to lag screw *C*. In order to reach the low-resistance wetted surface of the pole *D*, as shown in section *N–N*, the currents must flow through the dry, high resistance areas on the back of the pole.

The second path is indicated in the top view of the structure. The leakage currents might flow from the right-hand insulator in direction *A* to the edge of the wetted conducting surface of the arm at point *E*. They must then flow thru the dry, high resistance, shadow zone in order to reach the thru bolt, the outer end of which is terminated in the wet conducting surface *D* of the pole.

Voltage concentration zones, therefore, exist between point *E* and the through bolt and on both sides of lag screw *C* in section *N-N*. These voltage concentration zones are subject to burning tendencies.

Laboratory tests on an arrangement electrically similar to Figure 2 have indicated that electrical breakdown will occur in the direction of the grain from point *E* to the through-bolt in preference to the circumferential direction from the lag screw *C* to the edge of the wetted pole surface.

The grain structure of the wood in the arm is usually continuous while in the case of the circumferential direction around the pole from lag screw *C* the surface may not be continuous. It is usually interrupted by checks or cracks in the pole surface. The presence of cracks in the pole surface requires a higher voltage to cause electrical breakdown across a given circumferential distance in comparison with an equal distance along the grain of the crossarm. Pocket burning may develop at both locations. However, I would expect a greater number of cases to develop at the dry shadow area of the pole on the crossarm in comparison with the lag screw *C* location.

Under light precipitation conditions in which evaporation from the wood surfaces, due to the I^2R loss of the leakage current flow in these surfaces, exceeds the precipitation rate, localized drying will take place at these areas and tree burning may develop across the dry sections. Figure 3 of the discussion illustrates this condition at the contact between metal attachment parts of steel pins or braces on arms or poles.

Remedial banding methods similar to those suggested by Cronin are presented in Figure 4 of the discussion. Bands have been located at all metal attachment points. These bands when applied snugly to the wood surfaces decrease the leakage current density at the current collection edges of the bands and thereby tend to avoid localized drying and subsequent tree burning at these locations. To accomplish this result it is necessary that the current collection edges of the bands make good contact with the wood surfaces. In addition, the pole bands provide low resistance shunt paths around the dry high resistance voltage concentration zones in Figures 1 and 2.

The presence of the pole and arm bands do not detract from the impulse insulation strength of the structure in an important degree. If wood braces are used in place of the metal braces in order to increase the impulse insulation of the structure, it is suggested that the banding procedure shown in Figure 4 be used at the insulator and brace attachment points on the pole and the crossarm. In addition, a shunting arrangement similar to that shown in Figures 18 to 21 of the paper, be included at the pole to arm junction.

In reply to Wickham's question concerning the series impedance used in Figures 4 and 9 of the paper, we varied the magnitude of this impedance during part of our nonreported tests. During these particular tests we maintained the applied voltage constant from the test transformer and varied the magnitude of the impedance. Once electrical breakdown had taken place across the dry, high resistance, voltage concentration zones, the current magnitude that flowed thru the combination of series impedance and wood structure was controlled principally by the series impedance. The current magnitude that flowed after electrical breakdown were 2, 5, 10, and 20 milliamperes depending upon the magnitude of the series impedance. The general location of the burn damage in all cases was the same. The higher current magnitudes produced a given amount of burn damage in a shorter time than did the lower current magnitudes.

I believe Wickham has suggested the proper explanation for wood burning under fog conditions in which no particular part of the structure may become more wetted than others due to the absence of air movement, vertical convection or otherwise. Under these light wetting conditions the junction between the pole and the crossarm would be expected to remain dry and, therefore, have high resistance. If this high resistance section occurs as a part of a series leakage current circuit, a voltage concentration will appear across it, possibly accompanied with electrical breakdown and pocket burn damage. This situation would be aggravated by the presence of a gap between the arm and the pole due to either loose hardware or a loose fit similar to the condition illustrated in section *M-M*, Figure 1. I would not expect the fog to penetrate into these confined spaces without the aid of air movement.

I wish to thank Andrew, Caswell, and Weaver for the description of their laboratory tests and their field experiences including the use of banding arrangements. Our research efforts closely parallel their laboratory work and the general test findings are in good agreement.

Oldacre has made several valuable suggestions as to desirable future research work on this subject. These points also constitute a good criterion to follow in selecting materials for transmission line use from present designs when it is desired to avoid wood pole burning.

Some Recent Developments in the PCC Car

S. B. COOPER
NONMEMBER

Synopsis: The PCC (Presidents' Conference Committee) car was developed about ten years ago as a result of a co-operative research program by the major transit operating companies and manufacturers. This paper briefly reviews the history and experience with the car and outlines the recent changes and improvements. New performance curves are included.

THE PCC car is the result of a co-operative research program started in 1929 under the name of the "Electric Railway Presidents' Conference Committee." Rising costs and declining revenues indicated the urgent need of improvement over existing cars and of some degree of standardization of design so that cars and their equipment could be produced in manufacturing quantities instead of in small individual lots.

The committee was formed by a group of the presidents of the larger city transit systems, and the activity was financed by contributions from these operating companies and from the principal manufacturers interested in the car and equipment business.

Professor Clarence F. Hirshfeld was selected as chief engineer. Under his direction the program began with a careful study of the characteristics of then existing cars, their shortcomings, and the specific need for improvement that would make the streetcar more efficient and appealing to the riding public and would put its design and construction on a manufacturing basis.

The work of the committee and the resulting car have been described in previous Institute papers. It is the purpose of this paper to review the progress and developments since the last papers were presented and to indicate the trends which further developments may be expected to follow.

The first PCC cars were ordered early in 1935, and during the years from then until 1944 about 2,500 cars were placed in service on 16 properties in the United States and Canada. This period covered the latter years of the depression and the early years of the war. It was recognized that following the war there would be an increased demand for equipment to replace older rolling stock worn out by intensive use during the war period. A program was started to review and evaluate the experience with the cars up to that time and to establish the objectives of further developments and improvements to be incorporated in the postwar designs. This program resulted in the production of a sample 1945 model car which was placed in service on the lines of the Pittsburgh Railways Company in October 1945. The principal improvements may be outlined as follows.

Body changes were made to improve passenger comfort and aisle width by making seat spacing and post spacing the same. This makes it possible to move the seat cushion closer to the side wall of the car and to obtain a greater effective aisle width. Standee windows now have been adopted as a standard feature, making it possible for the standing passengers to see out without stooping.

The slope of the windshield has been increased and this, together with improvements in the "shadow apron" over the operator's desk, greatly reduce windshield reflections and improve the operator's view of the street at night. The shape and location of the front corner posts have been altered so as to minimize the "blind spots" and increase safety. The operator's position has been raised and moved forward somewhat to give him a better view of the area immediately in front of the dash. Detail improvements in doors, door mechanisms, and so forth, tend toward easier entrance and exit.

In spite of the fact that the original PCC car had a system of ventilation that took 1,200 to 1,500 cubic feet per minute of air out of the car, it has been recognized for some time that further improvement in car ventilation was desirable. It was felt that a definite circulation of additional fresh air would add materially to passenger comfort.

As the result of a considerable amount of experimental development, a system of ceiling ventilation is now available as an optional feature. A longitudinal roof monitor with louvered sides extends almost the entire length of the car roof. This is divided by cross barriers into alternate intake and exhaust sections. Three or four vertical motor driven fans,

Figure 4 (left). Combined master and brake controller

spaced along the ceiling of the car, draw their air from the intake sections of the roof monitor and discharge it directly into the car through diffusion grilles. These grilles are so arranged so as to direct the air flow out along the ceiling line, downwards diagonally, and along the sides of the car to give a definite feeling of air movement but without direct blast or draft effect. The roof monitor and fan intakes are arranged to trap and drain moisture. The space between the ceiling and the car roof is used as an exhaust duct communicating with the outlet sections of the monitor. The fan motors are connected in series across the line and are arranged for thermostatic control of fan speed—the speed being increased with higher outdoor temperatures. At top speeds these fans introduce a total of 12,000 to 14,000 cubic feet of fresh air per minute into the car. Experience with this system to date indicates that it may be entirely possible to operate with permanently closed windows.

This ventilation system has brought with it a change in the motor-generator-blower system of equipment ventilation and car heating. The air exhausted from the car by the motor-generator blower now is drawn partly through air intake grilles in the side lining of the car in the area opposite the center doors and immediately above the motor-generator-blower compartment, and partly from the center door step-well through the space between the car floor and the accelerator support plate. The motor-generator set now has a blower on each end. Each of these two blowers has its runner and housing partitioned by a divider plate, giving in effect two sections to each blower. In each one, the outer section farthest from the motor-generator set draws its air through louvered openings in the outside of the car and discharges it into a duct under the car floor leading to the two traction motors on the adjacent truck.

The inner section of each blower draws its air from the car body through the paths described and discharges it directly into the equipment compartment over the accelerating and braking resistors. From this space it is blown into cross ducts just ahead and back of the step-well section, and then directed by the thermostatically controlled dampers either to outside air in nonheating season or to the longitudinal sill ducts on *both* sides of the car in the heating season.

Because in summer weather the car body is under pressure ventilation from the ceiling fans, the side sill heater ducts also serve as air outlets from the car, further improving body ventilation and avoiding any possibility of damper leakage permitting warm air entering the car from the equipment.

Auxiliary heaters are mounted in the air stream on the outlet side of the blowers so that in case of a blockade or in case of infrequent stop service, where acceleration or braking resistor losses are insufficient to maintain comfortable car temperature, these auxiliary heaters are cut in automatically.

The heating and ventilating control is arranged to provide a definite sequence of operation of auxiliary heat, damper control, and steps of ceiling fan speed so as to provide for proper heating, cooling, and ventilation of the car throughout the range of operating temperatures.

Important improvements have been made in braking. The cost, complication, and maintenance of compressor, reservoirs, valves, piping, and cylinders of the air brake system seemed out of line with the small amount of work required for completion of the stop below the speed of dynamic fade-out and for holding the car at stops. In addition, it had proved quite difficult to keep the brake levers and shoes of the air operated wheel brakes

from accumulating clearances caused by wear and consequent noise and rattles. These reasons led to investigation of other forms of supplementary mechanical brakes. In 1939 the St. Louis Public Service Company purchased 100 cars of the all-electric type. The performance of these and of the second hundred purchased in 1941 was so successful that the initial skepticism of the industry was overcome and all-electric operation now has been adopted as standard.

On this type of car the air operated shoe brakes bearing on the wheel tread have been replaced by drum brakes carried on the coupling at the motor end of the drive shaft. Two forms of brakes are in current production and use—an internal expanding and an external contracting. In either case, either of two forms of operating mechanism can be used—spring application and solenoid release or solenoid application and spring release, with special means provided for spring application in case of failure of control power. This makes it possible to do away with the former hand brake for parking the car in sidings or yards as, with either form of brake or operating mechanism, opening the brake solenoid control circuit gives a spring applied brake without battery drain.

The necessity for finding room for the brake drum at the drive end of the motor was what first brought forced motor ventilation into consideration. The traction motor was shortened by omitting its internal ventilating fan. Since that time the obvious advantages of forced motor ventilation have become more generally recognized, and no doubt it would be continued today for its own merits entirely aside from the question of brake drum space. Forced ventilation keeps the motor under pressure, thus tending to keep dirt and water out rather than sucking them in as under "natural" ventilation. Also, the uniform continuous flow of cooling air independent of speed has proved much more effective than the widely fluctuating amount of air resulting from the internal fan at varying speeds.

While the original spring solenoid brake in St. Louis was quite successful, it was felt that for general application as standard equipment for hilly as well as flat cities a brake of greater holding power was necessary, and also that the drum brake should have sufficient thermal capacity for making the stop in case of failure of the dynamic brake. It seemed obvious that the drum brake would have the best chance of success in general application if its normal duty were reduced to the lowest possible level.

This led to the development of "extended dynamic" braking, wherein the dynamic brake is carried down almost to standstill, actually to about one mile per hour. This development was carried out with the co-operation of the engineers and staff of the Pittsburgh Railways Company and has proved remarkably successful. This limits the normal duty on the drum brake almost entirely to holding at stops and therefore reduces the wear on shoes and drums to a point within the practical limits of a short travel device like a solenoid.

Improvement also has been made in the "easy shut-off" by introducing resistance into the circuit before opening the line switch. This feature adds materially to passenger comfort during "on and off" operation behind slow traffic or with the nervous type of operator who, in spite of training and instruction to the contrary, will start and shut off two or three times while waiting for the traffic light to signal "go."

A combined master and braking controller simplifies installation and maintenance by providing permanent line up between the limit relay and the cams on the power and brake controllers.

The trend at present is toward the use of deion type circuit breakers in place of fuses for both 32- and 600-volt circuits.

A trip is indicated by the position of the handle, making it easier for the operator to locate quickly the circuit in trouble. Pushing the handle to "off" and then to "on" is easier and quicker than hunting for and replacing fuses.

Detail improvements have been made in the motor—a longer commutator permits larger brush area and increased brush life. Greater protection over the front commutator V-ring minimizes the damage resulting in case of motor flashing. Better insulation on both armature and field coils has lengthened coil life and reduced chances of breakdown.

Many control details have been improved as a result of the accumulated experience with the earlier cars. Silver faced wiping type control fingers and interlocks, improved type limit relay contacts and similar developments have increased reliability further.

Improvements in wiring and layout worked out in co-operation with the wiring committee and the engineers of the car builders have resulted in better equipment arrangement and installation and reduction in the number of pieces to be housed, mounted, and wired.

A new design of truck has been completed so there are now two sources of supply.

Car Performance

With the various modifications, car weights have tended to increase. At the present time standard single-end single-unit cars are coming through at about 36,000 pounds empty weight. Also, the equivalent weight addition for rotational or flywheel effect has been increased by the addition of the drum brake on the drive shaft and by some increase in the weight of the resilient wheels. Car performance based on these current weights and on the corresponding rates of acceleration and braking are shown on the accompanying curves.

Figure 5 shows the speed time and distance curves for a 36,000-pound car with an average load of 6,000 pounds up to balancing speed on level track.

The balancing speeds on grades up to 12 per cent are shown in Figure 6.

Schedule speeds and propulsion power consumption for varying stops per mile from 4 to 12 are shown in Figure 7. These are based on an acceleration rate of 3.5 miles per hour per second, dynamic braking at 3.15 miles per hour per second, coasting for 25 per cent of moving time and 7-second stops.

All curves are based on train resistance curve shown in Figure 8 plus six pounds per ton for resilient wheel resistance.

The number of cars in service and on order is the best possible testimonial to their success. Table I shows the cars now in service and on order by properties. This seems quite an impressive showing when it is recalled that the period covered included the latter years of the depression and the war years with material and production restrictions.

There is still much transit rehabilitation work to be done. No doubt many existing car lines in smaller cities or secondary and cross-town lines in the larger cities will be changed over to trolley coach or motor coach operation. The modern street car, however, remains a most efficient vehicle for heavy trunk route service in the large cities, in the field where density of riding is too high for a 40- or 44-passenger vehicle and not high enough to justify real rapid transit subways. There is growing recognition of the fact that street congestion is largely a function of the number of vehicles, and attempting to handle large numbers of people in private automobiles or in small capacity transit vehicles is neither efficient nor economical. City planners now recognize the prime importance of mass transportation in our cities. Along with plans for freeways and super highways, consideration is being given to the needs of the great number of people who necessarily will continue to depend on public transit. In a number of instances, plans are being studied for rail rapid transit, in conjunction with the freeways, where stations are arranged for convenient interchange with feeder lines for local distribution.

The PCC car equipment already has been developed for multiple unit operation, first for Pacific Electric Railway in Los Angeles and later for Boston Elevated Railway. The 50 cars recently placed in service on Cleveland Transit System all are equipped for multiple operation. Couplers can be added whenever the contemplated plans for rapid transit are completed. The city of Shaker Heights has just ordered 25 PCC cars arranged for operation in trains on their system operating from Cleveland terminal over private right of way out into Shaker Heights.

Chicago Rapid Transit has on order four experimental articulated cars of PCC type modified for their type of service and other developments are under way toward the development of larger capacity trucks

Figure 8. Estimated train resistance

Davis-21 ton car. Resilient wheel allowance not included

and equipment to apply the basic ideas of the PCC to heavy service.

Foreign cities are showing considerable interest in this type of car, and it confidently may be expected that many cars of this type will be used abroad.

Future developments probably will trend toward weight reduction by the use of lighter metals, continuing effort for greater passenger comfort and appeal, and also for the simplification and the further reduction of maintenance and inspection work.

The results obtained certainly bear out the hopes and expectation at the start of the committee's program. The cars have shown great passenger appeal and have met with almost unanimous public approval. The advantages of standardized design of body trucks and equipment, permitting minor modifications without too great change in major tooling, have been obvious. To be sure costs have risen sharply, but so have all costs, and it is certain that even at today's costs the industry is obtaining cars at much lower prices than would have prevailed under the old system of small individual lots.

The PCC car has justified fully the time, effort, and money spent on its development and has established itself as an efficient and attractive vehicle for the transit industry.

Discussion

John C. Aydelott (General Electric Company, Erie, Pa.): Cooper has mentioned the reason why forced ventilation was adopted for the traction motors of the Presidents' Conference Committee car and some of the good points of this system. It may be in order to say a few words in general in favor of self-ventilation, that is ventilation by a fan mounted on the shaft of each motor armature.

It is interesting to compare the amount of dirt which accumulates in two different types of motors in the subway in New York, apparently as a result of the system of ventilation. In both cases the motors referred to are modern high speed motors, those which are force ventilated are, in fact, an adaptation of the Presidents' Conference Committee car equipment and have been observed to be much dirtier than those on other equipments which are self-ventilated. Cooper speaks of the "widely fluctuating amount of air resulting from the internal fan at varying speeds". Apparently, the occasional high velocity blast of air which passes through the self-ventilated motors at high speed scavenges the dirt from the motors much more effectively than does the relatively slow steady stream of air passing through the forced ventilated motors. The effectiveness of both systems of ventilation as far as cooling is concerned is attested by the fact that there have been very few insulation failures in either application.

The provision of clean ventilating air is not an exclusive feature of the forced ventilation system. When the motors on the Presidents' Conference Committee cars were self-ventilated, ducts were provided to bring relatively clean ventilating air to the motors and this is always a possibility if considered worthwhile when self-ventilated motors are used. Cooper's point that pressure in these ducts insures greater cleanliness than suction is well taken but the use of ducts even under vacuum has been shown to be far superior to drawing in the air directly at the motor inlet when the motors are in a dirty location.

Self-ventilation of traction motors will probably find many applications for many years to come. High speed motors in particular lend themselves to the use of self-ventilation. Certain double reduction motors recently developed for use on industrial diesel locomotives are self-ventilated and have proved to be very successful with this type of ventilation. The fact that the motors are used with double reduction gearing is important as it means that even at very low locomotive speed the motors are revolving rather rapidly and ventilating themselves very effectively. In many cases these motors are used one to a locomotive and the simplicity of the self-ventilation system as compared to the use of a separate blower and the necessary ducts is obvious. In addition to simplicity the self-ventilation system also has an element of certainty to recommend it. There are fewer places where the system can go wrong. Whenever the motor is turning over it is providing its own ventilation.

Forced ventilation has its uses but consideration should also be given to the lower cost and simplicity of the self-ventilation system where it can be used.

Cooper's paper is concerned primarily with Presidents' Conference Committee cars and Presidents' Conference Committee car equipment and in this connection he mentions several applications of this equipment to rapid transit service. It might be well to point out that the traction equipment now being developed for the new subway cars described in the papers presented by B. F. Cordts and J. J. Sinclair at another session of this meeting should also find wide use on other rapid transit properties in this country. This equipment developed for rapid transit use is more powerful than the Presidents' Conference Committee equipment and is capable of handling the somewhat larger cars and high speeds usually associated with rapid transit operation.

S. B. Cooper: Our experience with forced ventilation on the Presidents' Conference Committee cars is quite definitely contrary to that indicated in Aydelott's interesting discussion. Direct comparison of natural and forced ventilated motors, duplicates in all respects except ventilation, on similar cars in the same service in the same city shows a definite advantage of forced ventilation in

1. Cleaner motor interior.
2. Fewer motor failures due to moisture in bad weather.
3. Materially lower temperature rise.

There can be no question of the value of the duct arrangement used on the older Presidents' Conference Committee cars to supply "clean dry air" to the naturally ventilated motors. This drew air for motor ventilation from outside the skirt line at the ends of the body bolsters. This was a great improvement over the older method of drawing motor air from the under-floor area. We believe the present forced ventilation scheme provides an even greater step of improvement.

It should also be remembered that the forced motor ventilation on the Presidents' Conference Committee car required no additional blower motor as the motor generator set was already there with part of its mechanical load removed by the elimination of the air compressor. The only net addition, then, was a small increase in blower size and some additional duct work—surely a small price to pay for the marked benefits obtained.

So far as "certainty" is concerned, if the motor generator set should fail, the car should not be run in any case because of absence of resistor ventilation. Such failures have been quite rare and it is difficult to see how any other failure could interfere with motor ventilation.

Admittedly, many successful applications of self-ventilated traction motors have been and will, no doubt, continue to be made, especially where cost and simplicity are paramount considerations. However, where a driving means for the blower is already available, the net added cost and complication for forced ventilation seems very small in proportion to the obvious benefits.

I had no intention of implying that the Presidents' Conference Committee equipment could take over the whole rapid transit field. There are, however, some types of rapid transit or semi private right-of-way running where weights and service requirements are within the capacities of PCC equipment where advantage can be taken of this very interesting development.

Automatic Control of Air Switches for Line Sectionalizing and Load Transfer

F. W. RICH
ASSOCIATE AIEE

M. S. KIRWEN
ASSOCIATE AIEE

Synopsis: The considerations involved in the design and application of automatic control of air switches are discussed in this paper with the thought that they might be used to guide designers and engineers who encounter similar problems. Three air break switch control schemes are described and the diagrams involved are shown. These control schemes were designed to provide automatic switching as follows:

1. Load transfer with synchronism check interlock, using direct current for operation and control.
2. Line sectionalizing and subsequent load transfer, using direct current for operation and control.
3. Load transfer, using alternating current for operation and control.

The description outlines the operation of the various control devices for manual switching and for automatic switching which occurs during fault conditions.

IN the application of automatic switches for transferring load, consideration should be given to the relative costs of air break switches versus oil circuit breakers. This is especially true when the circuit or circuits under consideration, at some future date, might become the source for important load centers. It is not the intent of the authors to discuss the costs nor to outline the relative advantages of one type of switching scheme over another. It might be pointed out, however, that automatic air break switches can be installed readily in such a manner that, when the circuit conditions warrant, oil circuit breakers can be added and the original air break switches used for by-pass switching.

Paper 47-51, recommended by the AIEE committee on automatic stations for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted October 31, 1946; made available for printing November 25, 1946.

F. W. RICH and M. S. KIRWEN are both with The Commonwealth and Southern Corporation, Jackson, Mich.

The principal function of an automatic load transfer scheme is to transfer a load from a preferred source, upon failure of voltage on the preferred line, to an emergency source, thus restoring service to the station. The second function is to transfer the load back to the preferred source upon restoration of voltage on the preferred line. This latter transfer should be made without interruption to service which necessitates paralleling the two lines for a short time during the transfer.

The principal function of an automatic line sectionalizing and load transfer scheme is to first sectionalize the line by opening both line switches upon failure of voltage on the bus, followed by the closing of one of the switches when voltage is restored on one section of the line, thus restoring service to the station. If desired, normal service can be restored by additional provisions in the control scheme for closing the second line switch when voltage is restored on its section of the line.

In the design of automatic air break switch control schemes, the first consideration is the potential source to be used for operation and control. Some schemes require a source of potential independent of the lines being switched while others can be operated with duplicate sources, one connected to each of the two main transmission lines. Another important consideration is the completion of a transfer, once it is started, or to set up the control so that a transfer will take place when one of the lines is energized. Another consideration is flexibility. Power circuit conditions change rapidly and it becomes necessary to change the automatic control to meet the new requirements of the power circuits. The control scheme should be such that the new requirements can be met with the minimum number of changes.

In the installations which will be described the main power sources are protected by oil circuit breakers which are equipped with reclosing relays and the normal circuit protective relays.

Time delay features are incorporated in the air break switch control schemes to prevent unnecessary switching caused by transient faults and to co-ordinate the timing of the transfer switching with that of the source oil circuit breakers.

Automatic Control of Air Switches for Load Transfer With Synchronism Check Interlock—D-C Operation and Control

This control scheme (see Figures 1 and 2) includes the general requirements previously outlined for automatic load transfer schemes. There also is provided a synchronism check interlock to block an attempt to parallel the two sources during switching operations unless they are in synchronism.

Normal Conditions

Station *L* normally is served from station *OC* which in turn is served from a 69,000-volt transmission line connecting stations *OR* and *P*. Oil circuit breakers 488 at station *OR* and 588 at station *P* normally are closed and are reclosed manually after automatic tripping. Oil circuit breakers 177 at station *OC* and 188 at station *OR* normally are closed with control arranged for one immediate reclosure after automatic tripping and two time delay reclosures. The total reclosing cycle is approximately $2^1/_2$ minutes. At station *L* motor operated air break switch 152 normally is closed and 252 normally open with their controls arranged for automatic switching.

Automatic Switching for Fault Conditions

1. *Failure of Line Potential.* Failure of voltage on the incoming line from station *OC* causes, after a time delay of approximately three minutes, the opening

of switch 152 followed by the closing of switch 252. This switching is initiated by the de-energized contact of auxiliary line voltage relay *UV-X* which is normally energized through energized contracts of line voltage relays *UV*-1 and *UV*-2.

2. *Return of Line Potential.* Return of potential on the line from station *OC* causes, after a short time delay, switch 152 to close, which for a few seconds parallels the two sources, followed by the opening of switch 252, thus restoring normal service. This operation is initiated by the energized contacts of relays *UV*-1 and *UV*-2 and is interlocked with synchronism check relay *SCR*.

Failure of voltage on the incoming line from station *OC*, which caused the original switching operation, might have resulted from the tripping of breaker 177 at station *OC* or from the tripping of breakers 488 and 588 at stations *OR* and *P*. The instructions for switching on the 69,000-volt line after a trip-out call for first closing breaker 488 at station *OR* followed by synchronizing and closing breaker 588 at station *P*. Because of the possibility of the reverse switching operations, that is, closing switch 588 before 488, thus energizing station *L* from a different generating source, and in order to serve stations *OC* and *L* from station *P* in an emergency with switch 488 open at station *OR*, the automatic control at station *L* is provided with a synchronism check relay. This relay blocks an attempt to parallel the two sources during this switching operation unless they are in synchronism. One coil of the synchronism check relay is connected to the bus potential transformer and the other to one phase of the line potential transformers.

3. *Failure of Bus Potential Following Line Potential Failure.* Failure of voltage on the incoming line from station *OR* after switching operation 1 has taken place causes no further switching. If this conditions still exists when voltage is restored on the line from station *OC*, switch 252 will open and 152 will close. This operation is initiated by auxiliary line voltage relay *UV-X* and bus voltage relay *UV*-3.

4. *Failure or Restoration of Potential During Switching Operations.* In the foregoing three switching operations, it is assumed that the initiating voltage conditions continue until a switching operation is completed. In switching operation 1, if line potential is restored on the line from station *OC* before relay *TD* completes its timing cycle, no switching will take place. If line potential is restored after *TD* contact closes but before 152-*b* contact is closed, switch 152 will open, 252 remains open and 152 will reclose by the operation of relay *CX*-1*A* as in switching operation 3. In switching operation 2, if voltage again fails on the incoming line from station *OC* before the contact of the synchronism check relay *SCR* closes, no switching takes place. If voltage fails on this line after relay *CX*-1 has closed its contacts, switch 152 will close and 252 will open. Under this condition switching operation 1 will be repeated.

In switching operation 3, if voltage fails on the incoming line from station *OC* after relay *TX*-2*A* contact closes but before 252-*a* closes, switch 252 will open but will reclose by the operation of relay *CX*-2 as in switching operation 1.

Figure 1. A 1-line diagram of station *L* and connected system

Control Schedule

In the operation of the switch mechanism, the motor circuit is held closed mechanically and the brake is held in the released position until the mechanism has reached its full angular travel. It is, therefore, unnecessary for the control switch or control contacts to remain closed in order to complete a closing or opening operation.

Manual. Turn the "automatic-manual" switch 43 to the "manual" position. Since the manual operation of each switch is identical, the following description will be confined to the operation of switch 152.

To close or open switch 152, energize relay *CC*-152 or *TC*-152 by operating control switch *C*-101 or *T*-101. This operation closes contact *CC*-152 or *TC*-152, energizes the motor *M* and mechanically releases the motor brake. At the end of the closing or opening operation a cam unlatches contact *CC*-152 or *TC*-152. Contact *CC*-152 or *TC*-152 therefore opens and the motor brake is applied. Relay *CC*-152 or *TC*-152 is de-energized when control switch *C*-101 or *T*-101 is released or by the operation of contact 152-*bb* or 152-*aa*.

The air break switch also may be operated by means of a hand crank. For hand operation an interlock is provided in the motor and brake circuit which serves as a safety feature in the event manual operation of the switch is necessary. This interlock is attached to the emergency hand crank guard. The guard must be moved aside before the hand crank can be attached. This operation opens the motor circuit and releases the brake. A mid position of the guard is the locked-out position. In this position, the brake is engaged but the motor switch is open. The guard may be padlocked in this position so that it can be used as a lockout while working on the motor mechanism or on the line.

Automatic. With air break switch 152 closed, 252 open, turn the "automatic-manual" switch to the "automatic" position. Relay *UV-X* is energized

Figure 2. Schematic diagram of station *L*. Load transfer scheme with synchronism check interlock using direct potential for operation and control

through an energized contact of relays *UV*-1 and *UV*-2 in series.

Failure of Line Potential. Failure of potential on relay *UV*-1 or *UV*-2, or on both relays simultaneously, allows the de-energized relay or relays to open their energized contact, after a time delay, to de-energize relay *UV-X*. A contact of *UV-X* closes to energize relay *TX*-1 through contact 252-*b*. A contact of *TX*-1 energizes relay *TD*. After a time delay of approximately three minutes, *TD* contact closes to energize *TC*-152 to open switch 152. When contact 152-*b* closes, relay *CX*-2 is energized through the de-energized contact of *UV-X*. *CX*-2 contact closes to energize *CC*-252 to close switch 252. When switch 252 closes, relay *CL* is energized through contact 252-*aa*. An energized contact of *CL* energizes relay *SCR*.

Return of Line Potential. If, after switch 152 is open and 252 is closed, relays *UV*-1 and *UV*-2 close their energized contacts, voltage relay *UV-X* will be energized. If line potential and bus potential are approximately equal in magnitude and in phase, relay *SCR* contact will close to energize relay *CX*-1 through 252-*a*, *UV*-1, and *UV*-2 contacts. *CX*-1 seals in through one of its contacts. The purpose of this seal-in is to allow the transfer to be completed if line voltage fails during the transfer. Another contact of *CX*-1 energizes *CC*-152 to close switch 152. After switch 152 closes, relay *TX*-2 is energized through *CX*-1, 152-*a* and 252-*a* contacts. *TX*-2 contact closes to energize *TC*-252 to open switch 252.

Failure of Bus Potential. If, after switch 152 is open and 252 is closed, voltage fails on the bus and relay *UV*-3 closes its de-energized contact, no switching takes place. Subsequently, if voltage is restored on the line, relay *UV-X* is energized after a time delay through energized contacts of *UV*-1 and *UV*-2. Relay *TX*-2 is energized through contacts *UV*-3, *UV-X* and 152-*b*. *TX*-2*A* contact closes to energize *TC*-252 to open switch 252. After switch 252 opens, relay *CX*-1*A* is energized through contacts 152-*b*, 252-*b* and *UV-X*. *CX*-1*A* contact energizes *CC*-152 to close switch 152.

Automatic Control of Air Switches for Line Sectionalizing and Subsequent Load Transfer—D-C Operation and Control

This control scheme (see Figures 3 and 4) was designed for a station connected to a normally closed transmission loop and provides for first sectionalizing the line upon failure of voltage on the bus and subsequently transferring the load to one section of the line. One potential transformer on the preferred section of the line and one potential transformer on the bus are used for this scheme. If voltage returns on the station *OR* section of the line, the load will be transferred to this source. If potential fails to return on this section of the line within the time required for the line voltage relay to close its de-energized contact, the load will be transferred to the section served by station *W*. This control scheme is not fully automatic under all conditions. If transfer is first made to station *W*, restoration of voltage on station *OR* section of the line will close the loop automatically for normal operation. If, however, transfer first is made to station *OR*, the loop will not be closed automatically.

Normal Conditions

Station *FB* normally is served from a 34,500-volt closed transmission loop fed from station *OR*. This loop has automatic sectionalizing oil circuit breakers at station *W*. Oil circuit breaker 288 at station *OR* normally is closed with control arranged for one immediate reclosure after automatic tripping and one time delay reclosure. Oil circuit breaker 277 at station *W* normally is closed with control arranged the same as breaker 288. At station *FB* motor operated air break switches 152 and 252 normally are closed with control arranged for automatic switching for voltage failure and for voltage restoration.

Automatic Switching for Fault Conditions

Fault at A

1. Breakers 288 and 277 open and immediately reclose. If the fault is cleared, no further switching occurs.

2. If the fault is sustained, breakers 288 and 277 again are tripped.

3. After a time delay, air break switches 152 and 252 open. This switching is initiated by bus voltage relay *UV*-2.

4. Breakers 288 and 277 have a time delay second reclosure. (The elapsed time between the first and second reclosure is sufficient for air break switches 152 and 252 to open.) Breaker 288 trips and remains open and its recloser locks out. Breaker 277 remains closed and its recloser resets.

5. After a time delay, air break switch 252 closes (152 remains open) to restore service to station *FB*. This switching is initiated by the de-energized contact of relay *UV*-1.

6. When the fault is cleared at *A* and breaker 288 again is closed, air break switch 152 closes to restore normal service. This

Figure 3. A 1-line diagram of station *FB* and connected system

switching is initiated by the energized contact of relay *UV*-1.

Fault at B

1, 2, and 3. Same as for fault at *A*.

4. Breakers 288 and 277 have a time delay second reclosure. Breaker 277 trips and remains open and its recloser locks out. Breaker 288 recloses and its recloser resets.

5. After a time delay, air break switch 152 closes (252 remains open) to restore service to station *FB*. This switching is initiated by the energized contact of relay *UV*-1.

6. When the fault at *B* is cleared and breaker 277 again is closed, no automatic switching occurs. Manual switching at station *FB* is required to restore normal service.

Fault at C—Bus Fault

1, 2, and 3. Same as for fault at *A*.

4. Breakers 288 and 277 close on the time delay second reclosure and remain closed.

5. Relay *UV*-1 closes its energized contact to close air break switch 152. Breaker 288 trips and its recloser locks out. Switch 152 remains closed. Breaker 277 remains closed and its recloser resets. The station is de-energized.

Simultaneous Faults at A and B

1, 2, and 3. Same as for fault at *A*.

4. Breakers 288 and 277 have a time delay second reclosure. They immediately trip and their reclosers lock out.

5. After a time delay, relay *UV*-1 closes its de-energized contact to close switch 252.

6. When the faults at *A* and *B* have been cleared and both breakers 288 and 277 close to energize the line, air break switch 152 will close to restore normal service. Closing either 277 or 288, but not both, will cause no automatic switching.

Simultaneous Faults at A and C

1, 2, and 3. Same as for fault at *A*.

4. Breakers 288 and 277 have a time delay second reclosure. Breaker 288 trips and its recloser locks out. Breaker 277 remains closed and its recloser resets.

5. After a time delay, relay *UV*-1 closes its de-energized contact to close switch 252. Breaker 277 trips and its recloser locks out. Subsequent closing of breaker 288 causes no further automatic switching.

Fault at B or C Subsequent to a Fault at A

1. Breaker 277 trips and recloses twice if the fault does not clear and its recloser locks out. No automatic switching occurs at station *FB*.

Fault at A and C Subsequent to a Fault at B

1. Breaker 288 trips and recloses twice if the fault does not clear and its recloser locks out. No automatic switching occurs at station *FB*.

Failure of Voltage on Line Voltage Relay UV-1 When Switches 152 and 252 Are Closed

1. No automatic switching occurs.

Failure of Voltage on Bus Voltage Relay UV-2 When 152 and 252 Are Closed

1. After a time delay relay *UV*-2 closes its de-energized contact to open switches 152 and 252. Switch 152 immediately recloses. Switch 252 remains open. No other switching occurs.

CONTROL SCHEDULE

The operation of the switch mechanism is the same as previously outlined for the control scheme shown in Figure 1.

Manual. The manual operation of switches 152 and 252 is the same as previously outlined for the control scheme shown in Figure 1.

Automatic. With air break switches 152 and 252 closed, turn the "automatic-manual" switch 43 to the "automatic" position. Relay *CX*-1*A* will be energized through energized contact *UV*-2 and contact 252-*a*.

Failure of potential on relay *UV*-2 will allow the relay to close its de-energized contact after a time delay. Relay *TX*-1 will be energized through contacts 152-*a*, 252-*a*, and *UV*-2. One contact of *TX*-1 closes to energize opening relay coil *TC*-152 to open switch 152.

Another contact of *TX*-1 in series with contacts *UV*-2 and 252-*a* energizes relay *TX*-2 which seals in through one of its contacts and energizes relay *TD*. After switch 152 has had time to start opening, *TD* closes its contact to energize relay *TC*-252 to open switch 252. When switch 152 opens, relay *TX*-1 is de-energized by the opening of 152-*a*. Likewise, when switch 252 opens, relays *TX*-2 and *TD* are de-energized by opening of 252-*a*.

If, after switches 152 and 252 are opened, relay *UV*-1 has its energized contact closed, or again closes it before it has time to close its de-energized contact, relay *CX*-1 will be energized through energized contacts *UV*-1 and 152-*b*. *CX*-1 contact in series with 252-*b* energizes *CC*-152 to close switch 152.

If, after switches 152 and 252 are opened, relay *UV*-1 does not close its energized contact but after a time delay closes its de-energized contact, relay *CX*-2 will be energized through contacts 152-*b* and 252-*b* in series with *UV*-1 de-energized contact. A contact of *CX*-2 completes *CC*-252 closing relay circuit to close switch 252.

If, after switch 252 has closed automatically, voltage is restored to relay *UV*-2, the relay will close its energized contact to energize relay *CX*-1*A*. Subsequently, if relay *UV*-1 again is energized to pick up relay *CX*-1, *CC*-152 will be energized through contacts *CX*-1 and *CX*-1*A* to close switch 152. However, if closing of switch 252 does not re-energize *UV*-2 and consequently *CX*-1*A*, the energizing of relay *UV*-1 will cause no switch operation because of the fact that relay *CX*-1*A* is de-energized and its contact in switch 152 closing circuit is open.

Automatic Control of Air Switches for Load Transfer—A-C Operation and Control

This control scheme (see Figures 5 and 6) is designed to include the general requirements previously outlined for automatic load transfer. In addition, control devices are provided so that either one of the sources of power supply may be selected as the preferred source. The

Figure 4. Schematic diagram of station *FB*. Line sectionalizing and subsequent load transfer scheme using direct potential for operation and control

emergency line must be energized in order to perform an automatic transfer of load.

The operating and control potential is obtained from the line potential transformers. The complete control and operating equipment for each switch is located in the switch mechanism housing. Certain interlock wiring is provided between the switches in order to obtain proper sequence of control potential during switching operations.

Normal Conditions

Oil circuit breakers 188 and 288 normally are closed with controls arranged for one immediate reclosure after automatic tripping and two time delay reclosures. Line *A*, the preference line, has its motor operated air break switch 152 closed with control arranged for automatic switching to line *B* in the event of a voltage failure on line *A*. When normal voltage is returned to line *A*, switch 152 will close and switch 252 will open.

Automatic Switching for Fault Conditions

Fault at A

1. Breaker 188 opens and immediately recloses. If the fault is cleared, no further switching occurs.

2. If the fault is sustained, breaker 188 again opens and after a time delay recloses. If the fault still persists, the opening and reclosing cycle is repeated and the automatic recloser locks out.

3. During the previous switching, relays *UV*-1*A* and *UV*-1*B* closed their de-energized contacts. This operation energizes relay *TD*-202. The timing cycle of relay *TD*-202 is such that its contact will not close until after the automatic reclosing relay on breaker 188 has locked out. After the forego-ing timing cycle is completed, the energized contact of relay *TD*-202 closes and energizes relay *TC*-152. Switch 152 will open and the closing circuit for switch 252 is made through 152-*b*. Switch 252 therefore will close. During this operation, it is assumed that line *B* has normal voltage.

4. When the fault is cleared at *A* and breaker 188 is closed, relays *UV*-1*A* and *UV*-1*B* close their energized contacts to close switch 152. Closing potential is obtained from line *A* potential transformer.

5. Immediately after switch 152 is closed, a circuit is set up through 152-*a* to open switch 252.

Fault at B

With emergency line *B* serving station *X* and line *A* out of service because of fault conditions, switch operations are as follows:

1. Same as fault at *A*, except refers to breaker 288.

2. Same as fault at *A*, except refers to breaker 288 and station *X* is de-energized because line *A* is out of service.

3. In the meantime, if the fault has been removed from line *A* and breaker 188 again is closed, switch 252 will open and switch 152 will close, thereby energizing station *X*.

Fault at C

1, 2, and 3. Same as for fault at *A*.

4. The fault at *C* has not been removed; therefore, during the previous operation, switch 252 closed into the fault and breaker 288 opened. Breaker 288 immediately reclosed.

5. Same as fault at *A*, item 2, except refers to breaker 288 and station *X* is de-energized because line *A* is out of service.

6. When the fault is cleared, breakers 188 and 288 are closed by the operators at the terminal station. Switch 152 will close and switch 252 will open thereby restoring normal conditions.

Simultaneous Faults at A and B

1. Breakers 188 and 288 immediately trip and reclose automatically.

2. If the faults are sustained, the breakers again open and reclose after a time delay. If the faults still persist, the opening and closing cycle is repeated and the automatic reclosers lock out and prevent further automatic switching. During this time no automatic switching has occurred at station *X*. Station *X* therefore is de-energized.

Control Schedule

The operation of the switch mechanism is the same as previously outlined for the control scheme shown in Figure 1.

Manual. The manual operation of switches 152 and 252 is the same as previously outlined for the control scheme shown in Figure 1 except that each switch is provided with an "automatic-manual" switch 143 and 243.

Automatic—With Line A Preferred. With switch 152 closed, turn the "automatic-manual" switches to the "automatic" position. The "line preference" selector switch 95, located in 252 switch mechanism housing, should be turned to the "preference" position.

Failure of Line A Potential. Failure of potential on line *A* causes relays *UV*-

Figure 5. A 1-line diagram of station X

1A and UV-1B to close their de-energized contacts. Relay TD-202 is energized through de-energized contact UV-1B and energized contact UV-2A. After a time delay, contact TD-202 closes. Relay TC-152 is energized through energized contact TD-202 and de-energized contact UV-1A. This operation energizes motor M-152 and the switch starts to open. After the switch opens completely, relay TC-152 is de-energized by the opening of 152-aa.

Immediately following the opening of switch 152, a circuit is set up for closing switch 252. Relay TD-202 still is energized and its contact is closed. Relay CC-252 is energized through 152-b in series with contacts TD-202, UV-1B, and UV-2A. After switch 252 is closed completely, relay CC-252 is de-energized by the opening of 252-bb.

Return of Line A Potential. Relays UV-1A and UV-1B again are energized. Relay TD-102 is energized through contacts UV-1A and SS-X (of the line preference relay 83). After a time delay, contact TD-102 closes and sets up a circuit through contacts UV-2B and SS-X to energize CC-152 to close switch 152. Relay CC-152 will be de-energized at the completion of the closing operation by the opening of 152-bb.

Immediately following the closing of switch 152, a circuit is set up for opening switch 252. Relay TD-102 still is energized and its contact is closed. Relay CC-252 is energized through contact 152-a in series with contacts TD-102, SS-X and UV-1A. At the completion of the opening operation CC-252 is de-energized by the opening of 252-aa.

Automatic—With Line B Preferred. With normal conditions existing, turn the "line preference" selector switch 95 to the "emergency" position. Relay TD-202 is energized through contacts SS2-95 and UV-2A. After a time delay, contact TD-202 closes and sets up a circuit through contacts UV-1B and SS2-95 to energize CC-252 and close switch 252.

Immediately following the closing of switch 252, a circuit is set up for opening switch 152. Relay TC-152 is energized through contacts 252-a, TD-202, SS2-95 and UV-2A. At the completion of the opening operation, CC-152 is de-energized by the opening of 152-aa.

Failure of Line B Potential. Failure of potential on line B potential transformer causes relays UV-2A and UV-2B to close their de-energized contacts. Relay TD-102 is energized through de-energized contact UV-2B and energized contact UV-1A. After a time delay, contact TD-102 closes. Relay TC-252 is energized through energized contact TD-102 and de-energized contact UV-2A. This operation energizes motor M-252 and the switch starts to open. After the switch opens completely, relay TC-252 is de-energized by the opening of 252-aa.

Immediately following the opening of the switch 252, a circuit is set up for closing switch 152. Relay TD-102 still is energized and its contact is closed. Relay CC-152 is energized through 252-b in series with contacts TD-102, UV-2B and UV-1A. After switch 152 is closed completely, relay CC-152 is de-energized by the opening of 152-bb.

Return of Line B Potential. Switch and relay operations are the same as outlined in the two paragraphs following "Automatic—With Line B Preferred."

Figure 6. Schematic diagram of station X. Load transfer scheme using a-c potential for operation and control

Conclusions

The three control schemes described were designed to meet specific system operating requirements. However, other system requirements can be met readily with a minimum number of changes in the control wiring. It is advisable to keep the design of an air break switch transfer scheme simple and inexpensive as the load center might develop beyond the limits of air break switches. In this event it would be necessary to replace the air break switches with more adequate and more costly equipment such as oil circuit breakers.

Appendix. Nomenclature of Schematic Diagrams

a = auxiliary switch contact—closed when device is in energized or operated position

aa = auxiliary switch contact—closed when operating mechanism of main device is in energized or operated position

b = auxiliary switch contact—closed when device is in de-energized or non-operated position

bb = auxiliary switch contact—closed when operating mechanism of main device is in de-energized or non-operated position

AM-1 = automatic manual switch—contact closed in manual position

AM-2 = automatic manual switch—contact closed in automatic position

C = close contact of control switch

CC = air break switch closing relay

CL = auxiliary relay used to energize synchronism check relay

CX-1, *CX*-1*A* = auxiliary relays for closing switch 152

CX-2 = auxiliary relay for closing switch 252

G = green indicating lamp

LC = lamp cutoff contact on control switch

M = air break switch operating motor

R = red indicating lamp

SCR = synchronism check relay

SS-1 = line preference selector switch contact—closed when line *A* is preferred ("preference" position)

SS-2 = line preference selector switch contact—closed when line *B* is preferred ("emergency" position)

SS-X = line preference selective control auxiliary relay

T = trip or open contact on control switch

TC = air break switch opening relay

TD = timing relay with time delay closing contacts, instantaneous reset

TX-1 = auxiliary relay for opening switch 152

TX-2, *TX*-2*A* = auxiliary relays for opening switch 252

UV-1, *UV*-2, *UV*-3 = line or bus voltage relays

UV-1*A*, *UV*-2*A* = line undervoltage relays for line *A*

UV-1*B*, *UV*-2*B* = line undervoltage relays for line *B*

UV-X = line voltage auxiliary relay

25 = synchronism check relay

43 = control transfer switch

83 = selective control relay

95 = line preference control transfer switch

101, 201 = control switches

201, 202 = time delay closing relays

108, 208 = control power switches

111, 211 = control power transformers

127, 227 = undervoltage relays

127-*X* = undervoltage auxiliary relay

143, 243 = control transfer switches

152, 252 = air break switches

169, 269 = interlock switches—open only when crank is inserted to operate mechanism by hand

Discussion

G. E. Heberlein (Railway and Industrial Engineering Company, Jeannette, Pa.): F. W. Rich and M. S. Kirwen's paper is particularly valuable in illustrating solutions to very common operating problems, providing improved service reliability on low voltage transmission lines. Little has been published on the extent of automatic switching and sectionalizing schemes and few engineers appreciate how widely used are such automatic air break switching installations. In general terms, most of the larger eastern utilities, having a large number of 33-kv or equivalent transmission lines, have from a few to dozens of these installations. K. Reardan of the West Penn Power Company stated that his company has 43 automatic switching installations. I am informed that one of the southern utilities has made over 200 installations during the past 20 years. I would like to comment, summarizing the experience gained from various operating engineers as to their preferences and needs, regarding automatic switching equipment of this type.

The application of such equipment is, of course, to improve service for the least capital investment, commensurate with the value of service rendered. Such installations involve air break switches, voltage sources, and the automatic relay equipment. For the lower voltage distribution lines, potential transformers are relatively inexpensive and can be used to provide both voltage indication and operating source for motor operation. For the usual transfer installation, the operation is only required when one or the other line is energized and as such, the operating source is available. In many cases, sectionalizing has been accomplished by means of spring operated switches with motor reclosing after the line again becomes energized.

In addition to the transfer and sectionalizing equipment described in the paper, many utilities are using special forms of automatic switching equipment. These schemes include:

1. Sectionalizing on overloads, where an air break switch is used to open a live line on overload. Equipment used is usually post-type current transformers with induction-type overcurrent relays, with conventional motor operated switches. Such switches may be of a special type for air break load interruption.

2. Sectionalizing of a line after a predetermined number of overloads, such operation is a dead line switching, usually after one, two, or three trippings of the associated feeder breaker. Equipment used includes special relays to record the number of overloads and timing the resetting.

Other automatic switching schemes combining features of the above have also been used.

While operating requirements vary widely and sometimes complicated schemes must be used, engineers tend toward greatest reliability through the use of simpler relaying equipment. By using a motor mechanism with a clutch which disconnects the air break switch drive from the mechanism, including the limit and auxiliary switch, testing of the automatic installation can be done without requiring operation of the air break switch. This permits going through a complete sequence without disturbing the position of the air break switch or requiring the switching of any lines.

The authors show the use of switch *169* as well as some auxiliary relays to insure completion of certain sequencing. By using motor mechanisms with contactors equipped with sealing-in contacts, which become de-energized by the motor limit switch at the end of the operating travel and the use of electrically operated brakes, simplification can be attained.

In general, Rich and Kirwen's schemes have been used by the majority with some simplification attained through the use of some of the features outlined. More specifically, in these change-over and sectionalizing schemes potential transformers are connected to the incoming lines ahead of the air break switches and only two undervoltage relays are used. The change-over schemes are usually arranged that the back transfer from the emergency to the preferred line takes place by paralleling the lines in case the emergency line is energized. Otherwise, the emergency line air break switch opens up before the preferred line switch closes. Naturally, a synchronism-verifier, connected directly to the potential transformers on the two lines, is required when there is a possibility of the lines not being in synchronism.

These schemes have varied in timing from 20 cycles to 60 minutes, depending upon the system conditions. This requires specific relays for these timing purposes. When the time delay for the change-over is not over 80 seconds, a long-time, geared induction type undervoltage relay is used for timing. If the required time is over 80 seconds, or a predetermined accurate time is required for back transfer switching, instantaneous undervoltage relays in con-

nection with long range mechanical timers are used. For accuracy purposes, the timers are driven by synchronous motors and are supplied with a vibrator type rectifier in case an alternating current supply is not available. Wherever possible, the operating mechanism contactor coils are energized directly by the voltage relay contacts.

The general preference seems to be to forego the use of indicating lamps on the relay equipments as they are only valuable during the time of testing of the equipments. Most engineers seem to prefer the seal-in type of control so that manual operation is completed without the need for holding the control switch in the operated position.

The general acceptance of this form of automatic control indicates satisfactory and reliable operating performance. With such widespread usage of automatic equipments and the diversity of conditions and schemes used, a symposium of the existing practices and experiences would be desirable.

R. S. Smithley (nonmember; Duquesne Light Company, Pittsburgh, Pa.): The automatic control of air switches or nonautomatic breakers for line sectionalizing or load transfer on the system of the Duquesne Light Company is based upon the procedure which would be followed by an operator in restoring service. The schemes ordinarily do not check line potential before a transfer is made. In general, 3-phase potential from the low voltage side of the nonautomatic station bank is employed for the supply to the undervoltage relays. An arbitrary sequence of sectionalizing is set up based upon the probability of a permanent fault occurring in the longer line section.

Two schemes performing the same functions as the schemes used by the authors for automatic control of air switches for line sectionalizing and subsequent load transfer, and automatic control of air switches for load transfer only, will be contrasted with those of the authors.

Referring to Figure 3 of the paper, and using the authors' designation of stations and switches, the sequence of operations used by the Duquesne Light Company to restore service is as shown in Table I of the discussion.

The sequence at station *FB* is controlled by two undervoltage relays making their de-energized contacts at 15 seconds and 45 seconds. Should the station become energized before either of these timers close their de-energized contacts, the sequence of operation at station *FB* is discontinued. The air break switches or the nonautomatic breakers at station *FB* are operated from a battery.

The scheme used by the Duquesne Light Company for automatic control of air switches for load transfer accomplishes the same result as the authors' scheme illustrated in Figure 5. Referring to this figure, and again using the authors' designation of stations and switches, the sequence of operation to restore service is as shown in Table II.

The scheme of load transfer when the station is fed as a double tap normally operated from one of two lines, consists fundamentally of transferring the station to the reserve line after it is shown that the fault on the regular line is permanent. The transfer is made by means of undervoltage relays at the station *X*. Should the regular line be returned to service on the instantaneous reclosure, the undervoltage relays at station *X* will not have closed their de-energized contacts, and therefore station *X* will continue to be served from the regular line. The air break switches or nonautomatic breakers at station *X* are operated from a battery.

Normal running order is not restored after damage has been repaired for either of the schemes described above. It is felt that travelling operators will have to perform the necessary switching to block the equipment out of service before repairs to the damaged lines can be made. Therefore, these same operators will restore the lines or stations to their normal running order after the damage has been repaired.

Table II. Automatic Control of Air Switches for Load Transfer*

Station W	Station X
(Normal Running Order is with breakers *188* and *288* closed)	(Normal Running Order is with air break *152* closed, *252* open)
Breaker *188* trips	
Reclose *188* instantaneously	
Breaker *188* trips if fault is permanent	
	Open *152* in 15 seconds Close *252* after *152* opens

* The two lines to which the taps are made are not necessarily from the same station.

Table I. Automatic Control of Air Switches for Line Sectionalizing

Station OR	Station FB	Station W
Breaker *288* trips		Breaker *277* trips Reclose *277* instantaneously Breaker *277* trips if fault is permanent in either line section
	Open *252* in 15 seconds	
Reclose *288* in 30 seconds		
	If permanent fault is between stations *W* and *FB*, service is now restored to station *FB*	
If fault is permanent between stations *OR* and *FB*, breaker *288* trips		
	Close *252* in 45 seconds Open *152* in 45 seconds	
		Close *277* in 60 seconds
	If permanent fault is between stations *OR* and *FB*, service is now restored to station *FB*	

S. C. Killian and **M. Stene** (Delta-Star Electric Company, Chicago, Ill.): Rich and Kirwen have made a worthwhile contribution to the literature by discussing in detail, line sectionalizing and transferring by air switches. Since this method of switching came into general use only a few years ago, there has not been a completely detailed sequence of operations for any particular scheme available for reference. Only manufacturers had literature available and that covered more generalized cases than those the authors have analyzed. Sectionalizing and transferring by this means presents an economy as compared to oil circuit breakers and more use of this method will doubtlessly be made, especially when lines are pulled into lightly loaded areas and where revenue does not justify the use of more expensive oil breakers. Other combinations of switching are being devised regularly, all based somewhat on the theory outlined by the authors. As an example, in a ring system, the scheme can be used to isolate a faulted section by progressive reclosing and then locking out.

With specific reference to each of the automatic switching sequences described in this paper, the following may be of particular interest. In the event of a bus fault at station *L*, Figures 1 and 2, breakers *177* and *188* will lock out. If either or both of the 34.5-kv lines have other load taps, the addition of a sequence lockout may be desirable to prevent complete outages at these load taps. The sequence lockout provides for automatic opening and lockout of both switches in the event of immediate voltage failure when either switch closes automatically. With the potential transformers located as shown in Figure 1 of the paper, this sequence lockout would apply only on closing switch *152*. However, both switches would be locked out, so that service could be restored to other load taps on both 34.5-kv lines. This sequence lockout is automatically reset when either switch is manually closed to a live line.

Referring to Figures 3 and 4 of the paper, it is presumed that the potential transformer is located on the low side of a transformer connected to the bus and that this was dictated by cost considerations. The authors state that this scheme is not fully automatic under all conditions but it is obvious that if both potential transformers were also located on the line side of the switches, fully automatic operation could be obtained.

It should be noted that the a-c load transfer scheme, Figures 5 and 6 of the paper, with the addition of a synchronism check relay will accomplish the same switching sequences as shown in Figures 1 and 2 without the need for a d-c source. This scheme

Figure 1

using alternating potential for operation and control has been used by our company. Motor mechanisms for this application have been built with oversize housings with space available for relays and control switches. Two such mechanisms are used for an alternating transfer scheme, or with slight modifications, for the load transfer scheme shown in Figure 6 of this paper.

The automatic switching schemes described by the authors are for single-phase control only—that is, one potential transformer for each line. The use of two potential transformers for ungrounded systems or three for grounded systems should be given consideration. We have had several instances in which single-phase control was chosen and failure to operate and consequent outage has resulted when line wires have broken. Additional potential transformers and relays have then been installed to prevent such failures.

The authors have made no mention of switching schemes using fault current through current transformers as a means of locating and clearing faulted line sections. A typical method using three motor-operated air switches is shown in Figure 1 of the discussion. The tap in this case is on a tie line with all switches normally closed. One potential transformer is used on each line and a current transformer on the load tap. Switches *1* and *2* open on loss of voltage after time delay providing fault current has not flowed through the tap. Restoration of voltage to either line causes reclosure of one switch. A synchronizing check relay allows the second line switch to close only when line *1* and *2* are in synchronism. The switch on the tap opens only on loss of voltage after fault current has flowed through the tap current transformers. With fault current through the tap, subsequent loss of voltage within a predetermined interval of time causes switch *3* to open and lock out; switches *1* and *2* are locked in and remain closed for sufficient time to allow the breakers to reclose and restore service through the tie line.

The use of air switches and motor operating mechanisms for this type of service reflects the faith that has grown up in the utility field in these two devices. The air switch, expected to stand out in all varieties of weather year after year with little or no maintenance, has become a highly reliable piece of apparatus, as has the motor mechanism.

K. N. Reardon (West Penn Power Company, Pittsburgh, Pa.): The very splendid paper written by Rich and Kirwen concerning the automatic control of air switches brings to attention the automatic air switch as a device of efficiency and economy in the maintenance of power supply and in the location of faults on line sections. The authors have well covered three types of applications by incorporating in their control schemes actions and safeguards required by their system operating procedure. It is natural and customary for control engineers to design circuits to duplicate automatically the functions that would be performed manually by an operator. At first judgment, it seems that too many provisions have been included in the schemes to take care of reasonable eventualities. However, as stated in the authors' conclusions, the three control schemes were designed to meet specific system operating requirements. Simplicity of control scheme is recommended by them and with that recommendation everyone will concur. Sometimes an operating department tends to burden control specifications by demanding that the circuits cope with more unusual than usual situations. A reasonable balance of probability will often result in circuit simplification without sacrificing reliability and essential requirements.

The West Penn Power Company has been applying automatic switches steadily since 1925 when the first installation of a directionally controlled spring operated type was made. There are now in active service 43 automatic air switch installations of which 19 are of the sectionalizing type, 16 of the transfer type, 7 of the isolating type, and 1 of the by-pass type. Two are in 132-kv service, one in 4,000-volt service, one in 33-kv service, and 39 in 25-kv service.

The transfer type and the sectionalizing type have become definitely standardized by us. The transfer type is operated by an alternating current supplied from small transformers on the incoming line. The sectionalizing type is operated by a 48-volt battery supply. Relay and control equipment has been reduced to a minimum. Fortunately we have not found it necessary to use synchronism check relays nor have we, except in one instance, found it necessary to return a transferred customer automatically to a preferred source as soon as that preferred source became available. The customer remains on the source to which he is transferred until an operator manually restores him (without interruption) to the preferred source.

Upon loss of power the automatic transfer type station will always transfer itself to its second available source of power provided that that second source is energized. The automatic sectionalizing type station will always pick itself up upon whichever line becomes energized and will close the sections together if both become energized. If a fault occurs on the bus between the automatic air switches of either transfer type or sectionalizing type, both air switches will, after unsuccessful attempt to re-energize the bus, open and remain open until manual switching is performed. With both switches thus locked open it is evident that all sections of the line can be energized from their respective sources of power.

Our method of operation differs in an outstanding point from that of Rich and Kirwen. There is no need of co-ordination of timing between the operation of the breakers and the feed points in the operation of the automatic air switches, except that the breaker should not close until the air break switches have opened, that is, the first reclosure should not be less than about three seconds. We do not delay the operation of our air-switches until tests are made by the automatic breakers at the source stations. Instead, the transfer type installation at once transfers its load to the second source; the sectionalizing type at once opens both of its air-switches. The action in both cases is initiated by an undervoltage time delay relay set to close its contacts in one second at zero volts. The load of the transfer type installation is thus re-energized within three seconds; the load of the sectionalizing installation is energized after an interruption not exceeding about nine seconds. If both line sections become energized, the two air-switches will close restoring the entire line to service in the case of the sectionalizing type of installation.

F. W. Rich and M. S. Kirwen: The authors wish to express their appreciation to G. E. Heberlein, R. S. Smithley, S. C. Killian, M. Stene, and K. N. Reardon for their discussions of this paper and for their valuable contribution to the information available on the general subject of automatic control of air switches.

As emphasized by Reardon, the control schemes presented in the paper were designed to meet specific system operating requirements. No reference was made to the more general types of control schemes in use. The outline of the general control schemes presented by the discussers together with the operating experiences given is valuable data. Also the special automatic control features such as sectionalizing on overload, sectionalizing after a predetermined number of overloads, and the use of the fault current through current transformers as a means of locating and clearing a fault, should prove of interest to control engineers.

Conditions frequently arise which might justify the use of current transformers in the tap line to locate a fault on that line. In a transfer control scheme such a fault would cause an unnecessary trip-out on the emergency line. In cases where there is considerable exposure on the tap line and where fuses in the tap cannot be co-ordinated with protective relays on the main line breakers it would seem that this additional feature should be given consideration. Whether or not the additional motor operated air break switch suggested by Killian and Stene for this purpose can be justified is questionable. The control of the two motor-operated air break switches could be arranged to lock out in the open position, on overcurrent, for faults on the tap line.

Reardon indicates that, in the control schemes used by the West Penn Power Company, the operation of the automatic air switches is not delayed until tests are made on the line by the automatic breakers at the source stations. It would seem that the probability of a fault being cleared on the first reclosure of a source breaker would justify testing the line before an automatic transfer could take place.

The authors wish to clear up some points in the control schemes presented by them which have apparently been misunderstood. Killian and Stene stated that these control schemes were for single phase control only, that is, one potential transformer for each

line. The control scheme shown in Figures 3 and 4 of the paper uses 3-phase line potential. Loss of potential, either single phase or 3-phase, will initiate a transfer to the emergency source. The transfer back to the preferred source will not be made unless 3-phase potential is available on the preferred line. The nature of the load at this station justified this additional protection. Heberlein, in commenting on the methods described by the authors for the completion of certain sequencing, has apparently overlooked the fact that motor mechanisms with contactors equipped with sealing-in contacts which become energized by the motor limit switch at the end of the operating travel are employed in these control schemes. Also Heberlein overlooks the fact that *169* and *269* are interlock switches which are open only when the crank is inserted to operate a mechanism by hand.

The discussions indicate that automatic air switches are used extensively to improve service with a nominal capital expenditure. They also indicate that for many applications the control schemes have been standardized by some operating companies and that for other applications the control schemes must be designed to meet the specific operating requirements.

Recent Developments in Track Brakes and Drum Brakes for PCC Cars

S. J. VOUCH
NONMEMBER AIEE

ONE of the factors which has made the President's Conference Committee car so successful is the effective braking system which has been incorporated into its design. This paper explains details of construction and characteristics of two component parts of the braking system—the magnetic track brake and drum brake, which recently have undergone extensive design changes.

The braking system often is taken as a matter of course while actually it is of great importance in that it permits the operator to use the accelerating and speed characteristics of the equipment to their fullest extent with confidence that he can stop as fast as any vehicle in his path. Without this confidence the operator would proceed in a timid fashion accelerating at a lower rate and running at reduced speed so as not to be taken unaware by some unexpected change in traffic conditions requiring a quick stop. As a consequence schedule speed would be reduced because the operator would not be able to use with safety the schedule ability provided by the motive equipment.

The major portion of the braking duty is performed by the motors acting as generators to produce a dynamic brake down to a car speed of about one mile per hour at which point the drum brakes automatically take over as the dynamic brake fades out. These two forms of braking depend upon the adhesion between the wheels and rails for their effectiveness, but the track brake presents an entirely separate friction surface to the rail, making it an important emergency brake particularly under slippery rail conditions. It is brought into play whenever the operator depresses the brake pedal beyond the maximum dynamic brake position, and thus can be applied any time operating conditions warrant its use.

Magnetic Track Brake

The track brake system includes four electromagnetic brake shoes, a controller, and resistances for varying the excitation from the car battery. Each shoe normally is held in equilibrium by a pair of springs so the bottom of the shoe is about three-eighths inch above the rail surface, the shoe being suspended between the wheels on one side of the truck, as shown in Figure 1. In effect the shoe is a long narrow electromagnet consisting of a coil held between fixed steel side plates to which are bolted renewable steel wearing strips as indicated in Figure 2. When the coil is energized from the 32-volt car battery it is pulled down to the rail by its own magnetism, gripping the rail with a force proportional to the current flowing in the coil.

The two shoes on each truck are tied together mechanically by a steel framework which holds the shoes in alignment along the rail and also provides a rigid surface so the drag exerted by the track brakes can be transmitted to the truck structure.

Because of the exposed location of the track brake shoes, the coil is subjected to direct wheel wash and in the winter months this may include salt water splash, slush, snow, mud, and so forth. During inclement weather the coil receives a constant barrage of these elements, any one of which may be detrimental to its continued functioning.

Previous construction included a steel spool body on which the coil was wound, with a copper strip encircling the winding; the whole assembly being put through a vacuum varnish treatment for waterproofing. In order to provide a better protection against failure from the causes mentioned a new method of coil construction has been developed wherein the coil is encased in a nonmagnetic stainless steel shell hermetically sealed to prevent the entrance of foreign matter.

The author wishes to acknowledge the assistance of J. F. Tritle, designer of the braking equipment described, in preparing this paper.

Figure 2. Cross section of track brake shoe

Accelerated life tests on coils of this construction indicate this improvement will result in greatly increased reliability in service. Figure 3 shows a cross section cut from a completed coil with the winding and method of sealing the edges of the case visible. Among other problems encountered in working out this construction was a suitable means of bringing the power lead through the case (the negative lead is grounded internally). This was

Figure 3. Section cut from completed track brake coil to show method of sealing edges of case

accomplished by building a female receptacle in one end of the case so a plug connection could be used on the end of the cable. A gland nut and tapered rubber bushing provide a seal at this point. This construction is of value in that it also permits easy replacement of damaged leads.

Figure 4 shows a typical pull characteristic, measuring the force required to pull the shoe from a machined surface on a 130-pound rail as the coil excitation is

Figure 4. Typical pull curve for track brake shoe

varied. While this type curve forms a useful basis for comparing characteristics of various designs under static conditions, it does not give a true picture of performance under service conditions, mainly because of two variables, rail condition and car speed.

It has been found that the surface of the shoe soon conforms to the contour of the rail head after it has been in service for a while, which results in greater retardation because of the reduction in air gap when the shoe is in contact with the rail. However variations in rail condition over the system will produce some variation in re-

Figure 8. Relative position drum brake and actuator in truck

Figure 9. Retardation curves, drum brakes alone

A—Low rate, brake applied at zero time, 10 miles per hour car speed

B—Intermediate rate, brake at zero time, 13 miles per hour car speed

sults. The speed at which the shoe slides over the rail also affects the rate of retardation because of the change in coefficient of friction with speed. A better picture of operation under actual service conditions may be obtained by referring to Figure 5. This shows a chart made with a recording accelerometer on a car and therefore takes into account the variables mentioned. The pattern is typical of the track brake, the deceleration increasing rapidly as the car speed is reduced and coefficient of friction increased.

Drum Brake on Propeller Shaft

Final stopping and holding of the car is accomplished by a drum brake mounted on each drive shaft, controlled by a brake actuator shown just above the track brake in Figure 1.

Previous designs included no means of graduation; that is, the brake was all on or all off. Consequently the maximum brake application was limited to a value that would not result in rough operation. This was satisfactory on properties where grade operation was not encountered, but with the general acceptance of the all-electric car it was necessary to provide increased braking ability with graduated application to permit operation on any street railway system in the country.

General requirements to be met were

1. Graduation without excessive variation in results over the range of brake lining wear.

2. Smooth build-up for normal stopping to provide good blending as the dynamic brake faded out.

3. Delayed release to prevent roll-back when starting on grades.

4. Fast application in emergency.

5. Automatic application on loss of low voltage power.

These requirements were met as follows:

1. A magnetic circuit design generally as indicated in Figure 6 produces pull characteristics as shown in Figure 7.

2. The inductance of the solenoid operating coil inherently results in a smooth build-up for normal operation.

3. By arranging the control to short-circuit the solenoid coils in the pedal release position, the flux decays slowly resulting in a gradual release of braking effort.

4. A separate holding coil when de-energized causes emergency springs to apply the brakes in 0.02 second as compared to normal application time of one second.

Although the drum brake normally is used only for the final stop and for parking, the control is arranged to apply it automatically if the dynamic brake should fail. The accelerometer charts show this condition and it is interesting to note the brake block material used has a nearly constant coefficient of friction with change in speed. This characteristic can be varied readily by changing the composition of the brake lining material to produce a rising coefficient of friction as car speed decreases.

Conclusions

The variety of braking means provided on the modern street car permits the operator to use the full capacity of the motive equipment with safety under present-day traffic conditions.

Design of an electric brake actuator has replaced the air brake used on street cars for many years. Automatic application of the drum brakes on failure of low voltage power has made it possible to eliminate the hand brake for parking. A total of 1,703 all-electric PCC cars are in service or on order.

Investigation of Silicone Insulation on High-Temperature Railway Motor

GEORGE GRANT, III
ASSOCIATE AIEE

T. A. KAUPPI
ASSOCIATE AIEE

GRAHAM LEE MOSES
MEMBER AIEE

Synopsis: Thermal aging and humidification tests are reported on a silicone insulated railway motor. This included 1,675 hours at a temperature of 285 degrees centigrade with 46 cycles of severe humidification. Loss of initial moisture resistance was observed but no operating failure occurred. No change occurred in the heat dissipating characteristics of the machine. Finally, the motor was dismantled and the insulation examined in detail. Thermal aging data are interpreted.

A comprehensive test program was begun in November 1943 to determine behavior of silicone insulating materials in electric motors. The program had as its main objectives to determine the relation between operating temperature and service life for silicone insulated motors and to obtain a comparison between the behavior of class *A*, class *B*, and silicone insulated motors when subjected to the same type of test cycle. Most of the equipment used consisted of induction motors, which have been operated at temperatures ranging from 200 to 310 degrees centigrade; this portion of the test program is not complete because of insufficient motor failures. One piece of equipment used, however, consisted of a silicone insulated street railway motor, and this motor has had over two years of accelerated testing.

The accelerated testing method used was based on the belief that moisture or humidification could be used to detect insulation faults. The testing cycle, then, consisted of periods of high-temperature operation of the motor, alternated with periods of severe humidification during which the condition of the insulation could be determined. In order to obtain test results in a reasonable length of time, the relatively high operating temperature of 285 degrees centigrade was selected. This temperature, chosen on the basis of laboratory tests and previous motor tests, proved to be sufficiently high to produce changes in insulation characteristics within 400 hours of aging. It was low enough, however, so that factors other than electrical insulation, such as commutation and bearings, did not interfere with the test.

Figure 1 shows the physical arrangement used to test the motor, loading it during the high-temperature run by a belt-connected generator.

Table I. Temperature Test Results

	Test Before Aging, October 29, 1943	Test After Aging, May 31, 1946
Line current	135	135
Line volts	302	294
Main field current	118	118
Speed (rpm)	1,820	1,822
Rise by resistance, C		
Main field	154	142
Commutating field	135	149
Armature	92.5	83.5

Description of Apparatus

The railway motor chosen for the test was the one used at that time on standardized Presidents' Conference Committee street cars. The motor has a normal continuous rating of 46 horsepower on 300 volts at 1,820 rpm in accordance with AIEE Standard 11. Under these conditions, the armature and commutating field currents are 135 amperes and the main field current is 118 amperes.

The mechanical design of the motor was unchanged including the copper sections and insulation thicknesses. The only changes made were to utilize silicone treated and bonded materials (mica, fiber glass, and asbestos) wherever possible. Full details are given in Appendix I.

Test Results

The test cycle consisted of a heat run at 285 degrees centigrade by resistance to age the insulation, followed, after cooling, by a severe humidification to facilitate the detection of possible insulation faults.

Figure 1. Silicone-insulated railway motor on life test in laboratory

Paper 47-53, recommended by the AIEE committee on land transportation for presentation at the AIEE winter meeting, New York, N. Y., January 27–31 1947. Manuscript submitted November 13, 1946; made available for printing December 5, 1946.

Figure 2. Insulation resistance data for various conditions of humidification plotted as a function of aging at 285 degrees centigrade

The humidification was followed by a drying run at relatively low temperature to eliminate the possibility of steam pockets causing faults which later might be interpreted as the result of aging. A full description of the procedure may be found in Appendix II.

The complete data are shown in the curves of Figures 2 through 7.

Figure 2 shows how the insulation resistance, both dry and humidified, varied with aging. It will be noted that the dry values tend to increase gradually to a maximum and continue with little change. But in the case of the humidified values, an initial high degree of moistureproofness is retained for something over 300 hours. At this point, the insulation resistance and moistureproofness quickly reach a minimum value which continues from there with little change.

Figure 3 shows that capacitance values reduce slightly with aging but offer little to correspond to the sudden loss in insulation resistance after humidification.

Figure 4 shows that a slight improvement in dry dissipation factor is gained upon aging. However, the values of wet dissipation factor show a retention of initial moistureproofness for approximately 350 hours, at which point it suddenly is lost.

Figures 5, 6, and 7 show the variation in insulation resistance, capacitance, and dissipation factor with time of humidification for three different stages of aging. These indicate, by their slope, the rate and, by ultimate values, the degree of moisture penetration.

Visually, the condition of the insulation did not change a great deal throughout the test period. Regular inspections were made before each humidification and a tendency for the silicone to lighten in color in the hotter spots was noted. No crazing, cracking, or loosening of the insulation was noted.

No trouble was experienced with bearings, grease, brushes, or commutation. This lack of trouble should be attributed to the cooling system of the motor. The cooling air was drawn in over the commutator, brush rigging, and brackets to bearing supports, effectively cooling them as well as the bearings.

After 46 cycles of heat and humidification, totaling 1,675 hours of operation at 285 degrees centigrade by resistance, the aging was discontinued and the unit examined Figure 8 shows the condition of the stator assembly at this point.

A temperature test disclosed that the heat dissipating ability of the winding had remained essentially unchanged by the severe accelerated aging test (see Table I).

A measurable increase in field resistance occurred during the test period; 2.23 per cent in the main field and 2.75 per cent in the commutating field. However, this is not of sufficient magnitude to cause any trouble and is, in fact, within normal manufacturing tolerances. Further, it must be remembered that this motor was run at a temperature well in excess of that contemplated for actual service to determine what does happen at such high temperatures and accelerated thermal aging. This high temperature definitely would accelerate resistance increase of the copper which is caused by oxidation.[6]

Table II. Dielectric Test Results

Motor Winding	Voltage: Held (One Min)	Voltage: Breakdown
Armature	2,200	2,600
Commutating field	2,200	2,600
Main field	5,400	5,800

Winding Breakdown Tests

Step-by-step (1-minute) dielectric tests were made on each winding separately with the results as shown in Table II.

After the armature was stripped, the individual coils were given a high potential test to breakdown between turns. This was a momentary test starting at 200 volts and increasing in 200-volt steps. The results of this test are shown in Table III.

Final Examination of Winding

Upon completion of all tests, the motor was disassembled and coils removed in

Figure 3. Capacitance changes with aging under varying humidity conditions

Figure 4. Effect of thermal aging and humidification on dissipation factor of silicone insulation

Figure 5. Effect of time of humidification on insulation resistance at several stages of thermal aging

steps to permit detailed examination of the insulation.

Figure 8 shows the condition of the field coils in the stator. In a number of spots, the final coat of varnish had begun to flake off. At the hottest spots (under wiring) there was evidence of more serious degradation of the varnish film as the color had lightened considerably and the varnish had become very brittle. However, in most places, the film was intact and in very good condition. The iron surfaces of the stator were well covered and essentially rustfree.

Figure 9 shows individual field coils with the ground insulation partially cut away. The insulation was flexible and still well bonded. No serious signs of degradation were observed.

A cross section of a main field coil is shown in Figure 10. The conductors were well bonded and the silicone filling cement (in the bevel) was solid. There was no evidence of insulation shrinkage or loosening throughout the coil structure.

The armature assembly is shown in Figure 11 in a partially dismantled condition. There were no visible signs of silicone insulation deterioration. The coils and insulation were flexible. Wires of the coils were well bonded. Engineers examining the motor were of the opinion that almost no aging had occurred on the armature insulation, which had operated considerably cooler than the fields. Only the wedges showed serious evidence of thermal aging and these were made of phenolic bonded asbestos laminate. The outer edges of the punchings were seriously rusted, indicating exposure to high humidity.

Discussion

The data on insulation condition show that a high degree of moistureproofness was attained in the motor as constructed. The loss of moistureproofness at approximately 350 hours of aging indicates that one or more faults developed in the continuity of the insulation structure permitting an increase in both rate and degree of moisture penetration to the conductors. However, additional aging produced little change in degree of penetration as seen in Figures 2, 3, and 4, but did produce an increase in rate as shown in Figures 5, 6, and 7. The fact that the rate of moisture penetration continued to increase steadily after 350 hours of aging indicates that new paths for moisture penetration were being developed by the heat aging. This was confirmed finally by the cracks and crazing discovered in hot spots during stripping of the winding.

Table III. Momentary Test Results

Breakdown Test Voltage	Number of Failures
200	2*
1,400	6
1,600	51
1,800	16

* Believed to have been damaged during removal.

If the rate of moisture penetration had not increased after the initial loss of moistureproofness, it would have been concluded that the 350-hour point was not a true turning point but an accidental one caused by an isolated crack in the insulation.

Comparing the various types of insulation measurements, it is seen that insulation resistance and dissipation factor give a true measure of the insulation condition only when the motor has been exposed to moisture. Capacitance changes are not great and do not appear to be significant either wet or dry. In view of this, when measuring the insulation condition of a silicone insulated motor, a low reading of insulation resistance will mean danger, but a high value does not mean the unit is in good shape unless it is known to have been exposed to high humidity. An excellent indication of condition is the ratio of change in insulation resistance or dissipation factor in going from a dry to a wet condition.

The concept of lightening in color is new with silicones. The organic types of resins used for insulation carbonize upon heat aging and produce free carbon which is black and a comparatively good conductor of electricity. However, silicones decompose into silica which is white and an insulator. Hence lightening in color is evidence of thermal aging with silicones.

Figure 6. Changes in capacitance with time of humidification at several stages of thermal aging

Figure 7. Dissipation factor changes with time of humidification at several stages of aging

Figure 8. Stator assembly after completion of 1,675 hours aging at 285 degrees centigrade

Furthermore data on this have been reported.[6]

In interpreting the thermal aging data from this test, the authors have followed the current concept of the thermal aging of insulation. This is based on the assumption that aging is a logarithmic function of temperature with the life being halved for a given temperature increment.[7] Pursuing this line of reasoning, the curve shown in Figure 12 was constructed as follows:

1. The point at which the loss of moisture resistance was noted is plotted as point *A*. This is considered "minimum life" at 285 degrees centigrade (by resistance).

2. The end of the test is plotted as point *B* and is considered as probable "average life" in view of the field winding condition at the end of the test.

3. Two parallel curves are drawn through these points (*A* and *B*) with a 12-degree-centigrade slope for 2-to-1 life expectancy change.

This is believed to be reasonably conservative in extrapolating toward lower temperatures as tests on materials and laboratory specimens indicate a value of ten degrees centigrade for half life.

Other tests have indicated that silicone insulation will have at least equal thermal endurance to class *B* insulation at 50 degrees centigrade higher temperature. Other recommendations to the AIEE have been made on this basis.[3] It therefore appears reasonable to examine such an increased temperature value in the light of this test. Adding 50 degrees centigrade to the current class *B* insulation standards for railway apparatus (AIEE Standard 11) would be equivalent to a peak temperature of 220 degrees centigrade or a normal temperature of 205 degrees centigrade (both observable values by resistance).

Figure 12 predicts that 36,000 hours operation at 205 degrees centigrade (observable temperature) will be required to reach the condition resulting in loss of initial moisture resistance, which is assumed to be minimum thermal life of the insulation. The average life represented by the final condition observed in this test would be at least four times as great.

In a necessarily simplified approach to an approximation of service life, it was assumed a railway motor is at normal operating temperature 25 per cent or less of each year. (This value was based on the advice of several railway application engineers.) On this basis, a silicone insulated motor would retain its original moisture resistance for over 16 years. This leads to the conclusion that, insofar as the silicone insulation is concerned, present temperature limits for class *B* insulation could be increased by 50 degrees centigrade for silicone insulation, and that reasonable thermal life is to be expected.

Conclusions

The tests reported herein are on a single railway motor which does not permit specific conclusions. However, the broad test program has indicated the following general conclusions:

1. Excellent initial moisture resistance.

Figure 9. Main and commutating field coils with insulation partly removed (after aging)

Figure 10. Cross section of aged main field coil

2. The moisture resistance is maintained at a high level during severe accelerated thermal aging.

3. Even after loss of the high initial moisture resistance, the insulation remains in operable condition throughout considerable additional thermal aging and exposure to extremely severe humidity conditions.

4. The thermal endurance indicated by these tests is such that reasonable life expectancy is predicted for silicone insulation at 50 degrees centigrade above the present temperature limits for class *B* insulation.

5. Improved thermal endurance of silicone insulation may be utilized to increase thermal life expectancy of insulation to many times that of class *B* insulation under the same temperature conditions.

Recommendations

Selection of specific railway temperature standards for silicone insulation should await further tests by other engineers, as it is recognized that a single test does not provide sufficient background for concrete recommendations of standards.

It would be of considerable value if design engineers would analyze various types of electric railway machines to determine what advantage in design may be gained from increase in operating temperature. This would permit sound evaluation of the over-all economics and aid in the selection of standard temperature limits for silicone insulated railway machinery. It may develop that the industry may not be able to utilize fully the temperature difference obtainable with silicone insulation. This may lead ultimately to the decision to set the standards at less than the indicated increase of 50 degrees centigrade and utilize the difference as added life expectancy or thermal margin of safety.

Therefore, it is the authors' recommendations that

1. Other engineers make similar accelerated thermal aging tests on silicone insulated apparatus for future discussion.

Figure 11. Partly disassembled armature after completion of test

2. Design engineers study various designs of apparatus to evaluate what advantage, if any, may be derived in size, weight, and rating through operation at higher temperatures.

3. The committee on land transportation sponsor further papers on this problem and discussions at future meetings.

Appendix I. Description of Apparatus

Armature Coils

Conductors were 0.144-inch square wire, glass covered, and treated with silicone varnish (*DC-990-A*). Ground insulation consisted of $2^1/_2$ turns of glass-backed mica wrapper 0.008 inch thick. The glass cloth was silicone-varnish sized and a silicone bond was used. Binder tape was fiber glass, sized with silicone varnish (*DC-990-A*). The coils were vacuum and pressure impregnated with silicone varnish at 70 per cent solids (*DC-990-A*).

Main and Commutating Field Coils

These coils were made of strap conductors, separated by a single thickness of glass-backed mica tape (0.007 inch thick, silicone bonded, and sized). Chamfer of the main field coil was filled with an asbestos and silica cement with a silicone resin bond. Ground insulation consisted of two half-lapped layers of thick glass-backed mica tape (0.007 inch thick, silicone bonded and sized). Binder tape was fiber glass sized with *DC-990-A*. These coils were vacuum and pressure impregnated with *DC-990-A* at 70 per cent solids.

Insulation details for winding the armature were made of glass-backed mica and asbestos cloth, silicone sized and bonded. For slot wedges the best available grade of asbestos cloth, laminated phenolic, was employed as no silicone bonded laminates were available at that time. Coils were soldered in the commutator necks with high melting solder (304-degree-centigrade solidus temperature).

Both armature and stator were dipped twice in *DC-990-A* silicone varnish (at 50 per cent solids). Subsequently, after preliminary testing, an additional dip and bake was applied to both armature and stator.

The Commutator

The commutator was insulated with mica bonded with a high-temperature synthetic shellac substitute. The bars were made of silver-bearing hard-drawn copper to avoid softening during the high-temperature bake or during operation. During all baking cycles, the commutator nut was loosened to relieve the V-binding from pressure strains.

Appendix II. Details of Thermal Aging Test

Heat Run

Each test cycle began with an aging heat run. The motor was overloaded and its ventilation restricted in order that the test temperature, 285 degrees centigrade, be reached as rapidly as possible. This was done to minimize the effective aging on the insulation during this time. Upon reaching 285 degrees centigrade, the ventilation was restored to normal and the load reduced to that required to hold this temperature in both fields. The temperature then was maintained for six hours in the initial runs. On succeeding runs this time was increased in steps. When a duration of 72 hours was reached, no further increase was made. During the 18–22 hours required to cool from the heat run to room temperature, readings of insulation resistance, capacitance, and dissipation factor were taken at 20 degrees centigrade intervals. These data were used for correcting the readings to 25 degrees centigrade.

In order to obtain the same temperature in the two fields, it was necessary that some of the current be shunted around the main field.

Heat Run Data

The following data were obtained on the heat run with 310 volts direct current, 1,650 rpm:

Main field = 285 degrees centigrade by resistance

Commutating field = 285 degrees centigrade by resistance

Armature = 180 degrees centigrade by resistance

Commutator = 150 degrees centigrade by thermocouple

Front bearing = 80 degrees centigrade by thermocouple in grease

Rear bearing = 95 degrees centigrade by thermocouple in grease

Outside frame = 150 degrees centigrade by thermocouple

Cooling air rise = 36 degrees centigrade (average of six thermocouples, 14 to 53 degrees centigrade)

Humidification

Upon reaching room temperature, the motor was placed under humidification for 24 hours. This was accomplished by covering the air exhaust and placing a tank over the air intake of the motor. In the tank a regulated quantity of air was bubbled through a bath of water five to ten degrees centigrade above ambient. This wet air then passed into the interior of the motor. Thus this method was extremely severe, as the winding acted as a condenser, causing the water in the air to form into rivulets and droplets on the insulation as well as produce a high humidity ambient atmosphere.

After 24 hours of humidification, the insulation resistance, capacitance, and dissipation factor were checked and a 5-minute high potential of 500 volts alternating current applied between windings and ground. This was followed by a 5-minute no-load run (125 volts, the maximum permissible without causing overspeed). The insulation readings and high potential then were repeated.

Originally it was planned that the insulation resistance, capacitance, and dissipation factor be studied on the main field, commutating field, and armature. However, it soon was found, because of the exposed lead ends, brush rigging, commutator, and other unavoidable bare copper, that the severe

Figure 12. Thermal aging curve interpreting test results

humidification caused these values in the commutating field and armature to vary beyond the range of available instruments. The complexity of these leakage circuits precluded satisfactory guarding. Hence the data here presented are those obtained from the main field whose leads extend outside the motor, thus avoiding leakage from bare copper inside the wet motor.

Drying

After the readings at the end of humidification, the motor was prepared for another heat run by drying it. This consisted of running 2 hours at 90 amperes, 250 volts producing a slow rise to 75 degrees centigrade. The load then was raised to 120 amperes, 300 volts producing an ultimate temperature of 130 degrees centigrade. This was held 8 to 16 hours. The motor then was considered ready to start a new cycle with the next heat run.

Preliminary Test

In order to bring the unit to a dry condition, it was run 8 hours at 120 amperes on 300 volts causing a temperature of 130 degrees centigrade. While cooling from this run, readings were taken as in the heat runs. Upon reaching room temperature, humidification was started and continued for one week. Daily readings of insulation resistance, capacitance, and dissipation factor were taken and the high potential test of 500 volts alternating current applied. At the end of the week, the no-load run (125 volts) was made. The insulation readings and high potential test were repeated and the motor dried as outlined earlier. This preliminary run provided a bench mark for comparison of data obtained as aging progressed. This 1-week humidification was repeated at 300 and 1,400 hours of aging as well as several 48-hour humidifications. These were run to broaden the over-all picture.

Appendix III

With reference to the values given in the paper the following items should be noted:

1. All resistance, insulation resistance, capacitance, and dissipation factor values are corrected to 25 degrees centigrade.

2. Insulation resistance values are 1-minute 500-volt direct current.

3. Capacitance and dissipation factor values were obtained with a low-voltage 60-cycle bridge.

4. Winding temperatures are all resistance values. The operating values on the main and commutating fields were obtained at frequent intervals by the voltmeter-ammeter method. These values were checked regularly by using the resistance at zero time, extrapolated from the cooling curve obtained with a Kelvin bridge. This bridge method also was used in obtaining the armature temperature.

Discussion

N. J. Greene (National Electric Coil Company, Columbus, Ohio): It is evident that the authors have devoted a tremendous amount of time and energy to the laboratory investigation of silicone treated and bonded insulating materials and windings. They have presented a summary of this information in a manner that should certainly stimulate further work along similar lines by both manufacturers and users who are desirous of increasing temperature rating of electrical apparatus.

Of the 300 odd silicone, mica, and glass windings we have supplied, ranging in sizes from fractional to 1,800 horsepower, about a half dozen have been returned for various reasons. This has provided an opportunity of determining how they are standing up and what some of their good and bad features may be. The operating results have been most gratifying. Of the six windings we have had occasion to examine, three of them provided particularly interesting information and they support in part, the laboratory investigation of the authors.

1. A 30-horsepower d-c crane motor operating on a very severe duty cycle provided an excellent test. Over a period from 1942 to 1945, the armature winding roasted out 21 times with an average of 50 days service after each rewind. The windings are class *B* insulation, of the usual mica and glass insulation, using conventional varnishes and bonds. On July 1945, the armature and field windings were replaced with silicone treated and bonded mica and glass insulated coils and operated satisfactorily for 312 days, at which time a bearing failure caused the winding to be damaged. Upon examination, the silicone, mica and glass insulation showed no perceptible deterioration. The same motor is again operating with silicone mica and glass and it has been in service now for 324 days. With the proper bearing maintenance, we would expect it to provide several years of service.

2. An 800-horsepower 1,800-rpm wound rotor induction motor driving an induced draft fan on top of a boiler in a powerhouse provided field test under high ambient temperature operation and also one where both a high speed rotating element and stationary element incorporated silicone, mica and glass insulated coils. After approximately six months operation, the rotor developed trouble due to squashing out of some of the silicone treated glass insulation on the rotor winding jumpers connecting to the slip rings. The winding itself was in excellent condition but the point of high mechanical stress had to be re-enforced with a melamine glass laminate supporting member in order to provide a safe job. It was interesting to observe that the silicone varnish showed no tendency of slinging off the rotor when operating at 10,000 feet per minute peripheral speed.

3. Of the several approximately 450-horsepower high-speed d-c traction armatures in service, one of them developed some difficulty at the commutator where the leads are soldered to the risers after 200,000 miles service. This provided an opportunity to remove several coils and thoroughly examine the condition of the band insulation, the coil insulation, and the copper at the coil corners, for copper fatigue. We had been concerned about copper fatigue at the high stress joints because of the almost complete annealing by virtue of the several bakes at 500 degrees Fahrenheit. It was a pleasure to learn that the insulation, copper, and the entire winding assembly was in by far the best condition that has been observed on an armature operating under similar conditions. There was almost a total absence of mica powdering as is customary where there is considerable winding motion and where conventional insulating materials are used in traction service.

M. R. Hanna (General Electric Company Erie, Pa.): The very excellent heat endurance reported in this paper is in full accord with results obtained on a number of machines of various types insulated in the same manner. The introduction of silicone has made possible a very considerable advance in the design of high-temperature insulation systems. However, to keep our thinking straight and to avoid possible costly failures from incorrect applications of silicone, we should bear in mind that silicone is not employed as a primary dielectric in these successful insulation systems. In other words, this is not silicone insulation but mica insulation treated with silicone.

The fact that none of the silicones now known are suitable for use as a primary dielectric does not minimize their importance in the mica-silicone insulation systems. Silicone treatment perfectly supplements mica by excluding moisture and preventing the shifting of mica flakes. Silicone is unique in its ability to perform this essential function at temperatures in excess of class *B* insulation operating limits.

The practical fabrication of mica-silicone insulations presents a number of new problems and it may be some time before the economics of this application of silicone become clear.

Graham Lee Moses: There were several points raised in the discussion which need some comment or clarification. It is true that the silicone varnishes in current use do not have as good solvent resistance as the best synthetic organic varnishes. However, those now available have solvent resistance equivalent to that of oleo-resinous varnishes which were reasonably satisfactory in this respect as demonstrated by many years experience.

A question was raised concerning the physical characteristics of silicone varnish

films at elevated varnish temperatures. It must be remembered that there are a number of different silicone varnishes having a variety of characteristics. Therefore, one generally can be selected having properties which are peculiarly suited to the application. *DC-993* silicone varnish has satisfactory hot film strength when properly baked. As in conventional organic varnishes no one silicone varnish has all of the desirable properties for every insulation application; therefore judgment must be exercised in the selection of the proper silicone varnish for each specific application.

Hanna's comments emphasize two important points on which there is general agreement.

1. Silicone insulation should include mica to provide the basic dielectric strength. The term "silicone insulation" was used to imply that silicone resin bonds and treatments are substituted for the organic resin bonds in an insulation system consisting of mica, glass, and asbestos in much the same manner as a class *B* insulation system. The term "silicone insulation" was used in this paper because of the lack of an AIEE insulation class. Currently, the Institute is in the process of defining and classifying this new form of insulation as class *H*.

2. All of the problems of applying and utilizing silicone insulations, especially mica-silicone combinations have not been solved. Many of the silicone insulation components are rather fully developed but there is still considerable work to be done on silicone-mica materials for use in commutators. Furthermore, the problem of attaching coil leads to commutators in railway type motors is a difficult problem requiring further attention. General usage on traction motor armatures is therefore further away than on some other types of electrical apparatus.

Automatic Switching Schemes for Capacitors

W. H. CUTTINO
ASSOCIATE AIEE

IMPROVEMENTS in design and reduction in cost within the past ten years have given increased recognition to the capacitor as an efficient, economical, and reliable generator of kilovars. The reduction in cost and increase in reliability resulted in more application investigations which revealed the economic possibilities of the capacitor as a useful tool for releasing system capacity, improving voltage regulation, reducing losses, and improving power factor.

The recognition of these many benefits has led to a rapid increase in the size and number of capacitor installations. When more and more capacitors are added to a system with widely varying loads, a situation may be reached where their effect becomes objectionable during certain operating conditions. It is therefore desirable to obtain the benefits of additional capacitor correction without the objectionable features. The maximum benefits can be obtained by adjusting the capacitor kilovars to the correct value at the proper time. When capacitor kilovars installed are greater than the light load reactive kilovars, it is usually desirable to have the capacitor kilovars reduced at light load to avoid objectionable overvoltage or excessive leading kilovars. The line losses are at a minimum when the capacitor kilovars are the same as the load kilovars. If voltage regulation is the primary objective, then the capacitor kilovars should be adjusted to hold the circuit voltage within the set limits. Unlike the ordinary voltage regulator, however, the adjustable capacitor improves the voltage regulation on both the supply and load side by reducing the current flowing in the supply feeders. If the primary objective is to keep the kilovolt-ampere demand to a minimum or to keep the over-all power factor within certain limits, the capacitor kilovars may be adjusted in response to a kilovar regulating relay or a power factor regulating relay. When the need for adjustable capacitor kilovars is established, then the question arises as to the most economical arrangement that will give the desired operating results.

The capacitor kilovars may be adjusted automatically by varying the voltage on the capacitor or by varying the amount of capacitors connected to the circuit. The amount of capacitors may be varied by automatically switching in equal or unequal steps in response to circuit conditions or they may be switched by the same switching means controlling the load for industrial plants. Switched capacitors also may be used to increase the effective range of a voltage regulator efficiently. In some instances, it is desired to have a kilovar generator which can furnish leading and lagging kilovars. This may be accomplished by a combination of capacitor, reactor, and automatic tap changing transformer; by a combination of capacitor and synchronous condenser; or by a combination of directly connected capacitors and reactors. These various schemes now will be discussed.

Indirectly Connected Capacitors

Variable Voltage Method

It is well known that the kilovars supplied by a given size capacitor vary as the square of the voltage applied. Consideration therefore has been given to varying the voltage applied as a means of adjusting the capacitor kilovars. The voltage applied to the capacitor may be varied by means of a tap changing transformer as illustrated in Figure 1*A* or by means of an induction regulator as shown in Figure 1*B*. By the use of either of these methods, the capacitor kilovars can be adjusted readily into small increments. The losses of the transformer or regulator add to the capacitor losses to substantially increase the over-all losses for the installation.

In general, reasonably coarse adjustment of the capacitor kilovars is found to be entirely satisfactory and the cost of directly connected capacitors with switches for each step is less expensive than the combinations of capacitor with tap changing transformer or capacitor with induction regulator.

If the repetitive switching duty on the breakers for directly connected capacitors cannot be tolerated because of a highly fluctuating load, then consideration should be given to capacitor with tap changing transformer or capacitor with induction regulator. In this connection, it should be remembered that if multistep automatic control is used to initiate the adjustment of capacitor kilovars, the kilovar increments should be in equal steps. To accomplish this with a tap changing transformer requires voltage steps of unequal values because the capacitor kilovars vary as the square of the voltage applied. If the capacitor kilovars are to be varied in $12^1/_2$-per-cent steps from zero to 100 per cent then the voltage steps must be 0, 35.4, 50, $61^1/_4$, 70.8, 79, 86.7, $93^3/_4$, and 100 per cent.

Directly Connected Capacitors

Switched in Equal or Unequal Steps

The capacitor kilovars usually are adjusted by switching the capacitors in equal steps as illustrated in Fgure 2*A* with a circuit breaker for each step. The control with master relay which will meet the operating requirements most economically will determine whether the capacitors are switched automatically in response to voltage, current, kilovar, or power factor.

Paper 47-54, recommended by the AIEE committee on automatic stations for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 15, 1946; made available for printing December 18, 1946.

W. H. Cuttino is with Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 1. Variable voltage method of control is seldom used for adjusting capacitor kilovars

A. Tap changing transformer varies voltage on capacitor

B. Induction regulator varies voltage on capacitor

Voltage control may be used to remove capacitors at light load if the supply voltage is regulated and the bus voltage varies owing to regulation. It also may be used for switching capacitors to regulate the feeder or bus voltage. Current control may be used to remove capacitors at light load if the supply voltage is nonregulated and the load power factor is reasonably constant with variation in loading. Kilovar control may be used to remove capacitors at light load when the supply or bus voltage is regulated or nonregulated and also may be used for switching capacitors to regulate kilovars or power factor. The band width or spread adjustment of the master relay of the automatic control panel always must be larger than the effect of the largest capacitor being switched. Maximum flexibility and minimum operating duty on the switch therefore are obtained by having the capacitors arranged in equal switching steps. This also permits the user to standardize on a certain size capacitor rating and vary the number of capacitor steps at a particular location depending upon requirements. If conditions change for any reason, the capacitors may be relocated as requirements may dictate.

To obtain a finer degree of control, it sometimes is proposed to switch the capacitors in unequal steps as illustrated in Figure 2*B*. Although a maximum number of kilovar values can be obtained with a minimum number of switches, there will be many more instantaneous changes and some of these will be greater than if the capacitors were switched in equal values. Figure 2*B* shows how the capacitors may be divided into three unequal values of 14, 28, and 58 per cent and switched to obtain seven values in steps of approximately 14 per cent. The maximum momentary disturbance occurs when switching from 42 to 58 per cent when the *C* switch closes and the *A* and *B* switches open, or when switching from 58 to 42 per cent when the *C* switch opens and the *A* and *B* switches close. The increased number of switching operations inherent with this scheme always cannot be tolerated. There are 22 switching operations for one complete cycle of switching for the unequal steps as compared with six for the equal steps. The *A* switch of the unequal step group operates 14 times during a complete cycle of switching, while the *A* switch of the equal step group operates only twice.

Figure 2. Directly connected capacitors divided into equal switching steps is a common method of adjusting capacitor kilovars. Capacitors divided into unequal switching steps seldom is used

A. Capacitors divided into equal steps

A, closed = 33 1/3 per cent
A and *B*, closed = 66 2/3 per cent
A, *B*, and *C*, closed = 100 per cent

B. Capacitors divided into unequal steps

A closed = 14 per cent
B, closed = 28 per cent
A and *B* closed = 42 per cent
C, closed = 58 per cent
A and *C*, closed = 72 per cent
B and *C*, closed = 86 per cent
A, *B*, and *C*, closed = 100 per cent

Switching Capacitors With Motors

In general, capacitors should be applied as near the load as practical. If it is found desirable to switch the capacitor with variation in load for an industrial plant, consideration should be given to distributing them out on the circuit and connecting them directly to the motor terminals as shown in Figure 3*A*. The capacitors then will be switched "off" and "on" with the motor without additional switching equipment.

The size of the capacitor switched with the motor switch should be selected to avoid excessive overvoltage caused by self-excitation and excessive transient torque. Charts[1] are now available listing the maximum capacitor size that should be switched with a given size motor. When capacitors are connected to the motor terminals, the line current drawn is less than without the capacitors. The overload devices, therefore, should be selected on the basis of the reduced line current if proper protection is to be obtained.

To avoid excessive overvoltage or excessive transient torque, it may be desirable in some cases to use a separate switch for the capacitor as shown in Figure 3*B*. In the interest of economy, the motor control may be used to initiate the opening and closing of the capacitor switch.

Capacitors Increase Effective Range of Voltage Regulator

When a voltage regulator is used for regulating line voltage, its effective range can be increased by adding a switched capacitor. The capacitor, unlike the ordinary voltage regulator, improves the voltage on both the supply and load side of the installation by reducing the current flowing in the supply feeders and lowering the losses in the circuit. The adding or removal of the capacitor increases or decreases the general voltage level of the circuit a given amount.

Figure 4 shows a regulator with limit switches arranged to initiate the closing or opening of the capacitor switch. When the regulator reaches the maximum "boost" position, the capacitor switch closes to increase the voltage level and the regulator and then backs up until the regulating relay is satisfied. However, as the regulator reaches the maximum "buck" position, the capacitor switch

Figure 3. Capacitors switched "on" and "off" with the induction motor for adjusting the capacitor kilovars

A. Motor and capacitor switched as a unit eliminating a separate switch for capacitor
B. Separate switches for motor and capacitor operated simultaneously by motor control

Figure 4. Switching capacitors extend effective range of voltage regulator

A. Limit switch on regulator closes when regulator reaches maximum boost position to close the capacitor switch
B. Limit switch on regulator closes when regulator reaches maximum buck position to open the capacitor switch

opens decreasing the voltage level and the regulator reverses its travel and backs up until the regulating relay is satisfied. If adding or removing the capacitor changes the voltage level five per cent, then the effective range of the regulator is changed by this amount.

If it is desired to minimize the voltage change produced by switching the capacitor as one group, then the capacitor can be divided into several smaller groups each with switches and let the limit switches initiate a sequencing device to obtain selective switching of the capacitor groups.

Supplying Adjustable Leading and Lagging Kilovars

Capacitor, Reactor, and Transformer Combination

Capacitors rapidly have been replacing synchronous condensers for providing bulk wattless power or kilovars for voltage regulation and power factor correction. There are many applications of synchronous condensers at the ends of power transmission lines where it is necessary to adjust the kilovars supplied over a wide range including positive and negative values. For this purpose, standard synchronous condensers are provided with 50 per cent lagging reactive capacity as well as 100 per cent leading reactive capacity and can be varied between these limits.

A capacitor, reactor, and tap changing transformer have been proposed for performing essentially the same functions as the synchronous condenser. One scheme is shown in Figure 5*A*. This involves a tapped shunt winding, a capacitor, a reactor, and a tap changing mechanism which can vary the capacity kilovars from 100 per cent of the capacitor rating to zero by changing taps. A transfer switch is provided to transfer from capacitor to reactor when the tap changer reaches the bottom of the travel, whereupon the same tap changer operating on the taps of the same shunt winding can be used to increase the lagging kilovars from zero to full rating of the shunt reactor. If the capacitor kilovars is 100 per cent and the reactor 50 per cent, this combination will cover the usual range of the standard synchronous condensers.

A very similar scheme was described by Butler and Foster.[2] This arrangement omitted the transfer switch and connected the capacitor in series with the reactor and the combination in parallel with the transformer winding. The common point between the reactor and capacitor is connected to the tap changer. Although this eliminates the cost of a transfer switch, the advantage is counteracted by adding operating losses and increasing the size of the transformer.

Directly Connected Capacitors and Reactors

The tap changing transformer equipment adds considerable expense to an installation. If the repetitive switching duty can be handled satisfactorily by a breaker and there are not a great number of switching steps required, then directly connected capacitors and reactors as shown in Figure 6 are less costly than the

Figure 5. Adjustable leading and lagging kilovars provided by capacitor and reactor with tap changing transformer or with capacitor and synchronous condenser

A. Tap changing transformer capacitor-reactor combination
B. Synchronous condenser and capacitor combination

Figure 6. Adjustable leading and lagging kilovars furnished by switching directly connected capacitors and reactors

Figure 7. A 1,260-kilovar 13.8-kv outdoor capacitor with oil circuit breaker and single step voltage control for automatic switching

schemes involving the tap changing transformer. It will be noted that transfer switches are added to permit one breaker being used for switching either a capacitor step or a reactor step. The directly connected capacitors and reactors eliminate the losses of the tap changing transformer and also have the advantage that they can be added to or subtracted from readily.

Capacitor and Synchronous Condenser Combination

A synchronous condenser lends itself well to control of kilovars where a large range of leading to lagging is required. It also provides a means of improving system stability or smoothing out voltage dip where these features are desired. Capacitors, however, are less expensive, easy to install, lower in losses, and are added to or subtracted from easily.

The combined advantages of the two types of equipment have been realized[3] by adding capacitors to an existing synchronous generator installation. The capacitor may be used primarily as a base correction with the synchronous condenser output varying to meet the variations of kilovar requirements with changing load conditions.

Figure 5*B* illustrates the combination of synchronous condenser and capacitor. If the load kilovar requirements vary over a wide range, it may be desirable to switch the capacitors automatically in addition to the variations obtained from the synchronous condenser. This can be accomplished by means of limit switches on the synchronous condenser control—one limit switch to close as the control approaches the maximum "boost" position to initiate the closing of the capacitor switch and another limit switch to close as the control approaches the maximum "buck" position to trip the capacitor switch.

Conclusions

1. Maximum benefits with increased use of shunt capacitors require that more consideration be given to switching them automatically.

2. The size and number of adjustable capacitor kilovars should be selected to keep the voltage, power factor, or kilovar demand within desired limits. Usually, coarse adjustment of the capacitor kilovars will meet the operating requirements satisfactorily. In this case, the small steps readily obtainable with the induction regulator or tap changing transformer are not a feature of importance.

3. Generally, economic considerations and average operating conditions favor switching directly connected capacitors in equal steps with electrically operated switches automatically controlled. Other switching schemes should be given consideration if the load consists of large motors with good diversity factor, which is usually favorable to switching the capacitors with the motor or if the expected repetitive switching duty is sufficiently high to make the application of breakers questionable.

4. Capacitors may be considered in combination with reactors or synchronous condensers for supplying leading and lagging kilovars.

5. The operating conditions and requirements will determine which type of automatic control should be used.

Laboratory Aids for Electromechanical System Development

GEORGE C. NEWTON, JR.
ASSOCIATE AIEE

W. T. WHITE
NONMEMBER AIEE

Synopsis: Laboratory aids for development of electromechanical systems are described in this paper. Standardized components for "mocking up" complex electromechanical systems have proved to be time-saving aids in laboratory work at the Sperry Gyroscope Company, Inc. Illustrations are shown of laboratory setups using these components and descriptions are given of the more generally used mechanical and electronic components.

THE PURPOSE of this paper is to describe a set of standardized components used by engineers at the Sperry Gyroscope Company, Inc. for mocking up electromechanical systems. These components enable laboratory tests to be conducted for such systems long before the completion of the product designs and the construction of pilot models. With the standardized components it is possible to construct a dynamic system similar to the electromechanical system of the product under development. Such a dynamically similar system is termed a "mockup" and the components are called mockup components.

The relation between the mockup and the system it represents is analogous to that between a "breadboard" of a radio receiver and the product receiver as finally manufactured. The breadboard receiver can be made to represent the production receiver as accurately as necessary by refining the networks used to study the effects of stray capacitance and so forth. Likewise, a mockup can be made to represent an electromechanical system as closely as desired by properly introducing stray effects such as backlash and elasticity in gear trains, nonlinearities in signal-producing elements, and various types of friction loading.

As currently practiced, the mockup technique is not an analytical tool in the same sense as differential analyzers,[1] transient analyzers,[2] network analyzers and the various mathematical methods[3] used in the analysis of electromechanical systems. It is not an analytical tool any more than pilot-model testing is. Rather, the mockup technique is a means whereby certain results, in the past usually obtained from tests conducted on a pilot model, may be anticipated by corresponding tests of a dynamically similar system which can be constructed and modified with relative ease. If pilot models could be built with a hundredth of the effort and in a hundredth of the time currently necessary, they would be used in preference to mockups and no need for mockups would exist. A mockup attempts to represent the actual system dynamics as closely as necessary so that the results obtained are truly indicative of system operation. However, for application of an analytical tool the system must be idealized, and the results may be significantly nonindicative of system operation.

To understand more fully the position of a mockup in the development of a product involving an electromechanical system, consider the phases through which such a development passes. Specification, conception, analysis, design, pilot-model construction, test, modification, and reproduction are the major phases. If a mockup phase were to be included, it would be inserted between the analysis and design phases. By adding this phase, which includes a certain amount of testing much benefit may result through

Figure 1. Demonstration servomechanism

Paper 47-52, recommended by the AIEE joint subcommittee on servomechanisms for presentation at the AIEE winter meeting, New York, N. Y., January 27-31, 1947. Manuscript submitted October 31, 1946; made available for printing December 4, 1946.

GEORGE C. NEWTON, JR. is with the Sperry Gyroscope Company at Garden City, N. Y.; W. T. WHITE is with the same company at Great Neck, N. Y.

improvement of design and the consequent reduction of expense and time lost in the testing and modification phases. It is to be emphasized that the mockup phase does not supplant the analysis phase and that any and all techniques ordinarily used in analysis also will be appropriate when the mockup phase is included. The mockup phase is merely a way of making the pilot-model dynamics available for test much earlier than otherwise would be possible.

It is recognized that the mockup technique has stimulated the development of a set of components which may be used for many purposes not directly connected with their original function. These components may be used in the construction of differential analyzers and other analytical aids. They may be used as an educational medium to help engineers and students appreciate more keenly the problems of dynamics.

The mockup components described in this paper are relatively simple in design; the fundamental ideas could be embodied much more elegantly. However, the best way to present the basic ideas seems to be by showing their present embodiment and allowing the reader to make his own abstractions.

Mechanical Mockup Components

Figures 1 and 2 illustrate mockup components in use. As can be seen, the components form a precision "mechano" set with an electronic addition. They may be classified broadly into mechanical and electronic categories. Together with a few special parts manufactured by the laboratory technician and special assemblies peculiar to the system being represented, such as electric motors, hydraulic apparatus, integrators, and gyroscopes, the standard components make possible the mocking up of almost any electromechanical system. After one is familiar with the components, the method of using them follows directly from the signal schematic of the system being represented; therefore this aspect of the mockup technique need not be discussed here.

The standardized mechanical parts are classified as

1. Foundational components, Figure 3.
2. Apparatus-mounting components, Figure 4.
3. Rotational components, Figure 5.
4. Bearing brackets, Figure 6.
5. Special hardware, Figure 7.

Only typical examples of the more frequently used items are shown.

Many of the features of these parts are obvious. They are simple in design, rugged, and easy to manufacture. But their form is not entirely arbitrary. For example, the base plates shown in Figure 3 appear arbitrary in design. They are nothing more than plates with holes

drilled in them; yet some of the thoughts entering into their design are

1. Material—should be lightweight, rigid, and have a reasonably hard surface.

2. Hole spacing—should permit flexibility of adjustment of all parts, yet not require more holes than necessary.

3. Tapped holes versus nuts and bolts—the convenience of not working below the plate must be weighed against the cost and disadvantages of tapped holes (such as dirt causing stripped threads and the impossibility of using T-slotted pedestals).

4. Size—the plates of various sizes should form a related series and individually be convenient in use with other components.

It was decided that slotted plates were not desirable because of the large portion of plate surface removed and because of cost. Aluminum alloy was chosen as the material. In particular *24ST* sheets, 5/8-inch thick, are used for all but the largest plates. A square hole-spacing of 1/2-inch center-to-center distance was selected after consideration of the other components. Drilled holes 9/32-inch diameter are used to pass, with ample clearance, 1/4-inch bolts. The size series 9 by 12, 12 by 18, 18 by 24, 24 by 36, and 36 by 48 inches was adopted; each plate's size is equivalent to two of the smaller size plates and one-half of the corresponding larger size plate.

Apparatus such as self-synchronized motors, small motors, and potentiometers are mounted on plates to which are fastened pedestals (see Figure 4). The pedestals have T-slots milled lengthwise to receive bolt heads. The nuts are tightened from below the base plate upon which the plate-pedestal assembly rests. The infrequent contingency of the pedestal slot not coinciding with a row of holes is met by clamping the pedestal with dogs, bolts, and clamp blocks shown in Figure 7. A universal pedestal with two T-slots is shown in Figure 4. This has tapped holes to aid in mounting apparatus which cannot be mounted by the plate method.

A basic consideration in the design of rotational components and bearing brackets is the shaft size. On the predication that the standard inch-type ball bearing would be used, it was decided to standardize on 1/4-, 3/8-, and 1/2-inch nominal diameter shafts. The greatest portion of the shafting of any mockup is of the 1/4-inch size. The shafting is stainless steel drill-rod, ground to a diameter sufficiently less than nominal to slide through a ball bearing without undue force. Standard short lengths are stocked, as well as commercial lengths, from which a desired nonstandard length may be cut; examples are shown in Figure 5.

The gears adopted for mockup use are 48-, 32-, and 20-diametrical pitch, $14^1/_2$-degree pressure angle. Most of the gearing is 48-pitch and attempts are made to stock these gears by 1-tooth steps from 10 through 200. Other pitches are stocked less completely. The number of gears stocked in any size is determined by expected frequency of use.

The fastening of gears to shafts has been a problem. Setscrews are easily shaken loose unless a type is used that mars the shaft. Provision of flats on the shafts is expedient but not entirely effec-

Figure 8

tive (grooves may be more effective but they are difficult to machine). The use of clamps and collet-type bosses has been very satisfactory. The clamps and bosses are shown in Figure 5. Bosses are machined in quantity and installed on gears by pressing (and pinning if necessary). With this design of fastening, round shafts are used and no flats or grooves are required.

Bosses can be used as collars in most situations. However, if space is limited, the simple ring collar shown in Figure 5 may be used. The latter is held by brass setscrews which do not mar the shafts.

An assortment of bushings to fit 1/4-inch bored gears to smaller shafts used on self-synchronized and other motors is valuable. Since the use of bushings ordinarily requires setscrew fastening of gears to the undersized shafts, the bushings are provided with holes to pass the setscrews (see Figure 5).

The bearing brackets shown in Figure 6 are designed to receive inch-type ball bearings. The standard brackets are designed for $2^1/_4$-inch shaft center height above the base plate. This permits swinging 48-pitch gears of more than 200 teeth. The base of the bearing block is T-slotted and may be used as a clamping surface. Generally, it is best to make mockups with all shafts in a single plane if possible. However, if shafts must pass over one another, or if a height different than $2^1/_4$ inches is used, standard brackets may be shimmed or recourse had to the adjustable-height bearing bracket shown in Figure 6. The larger bearing bracket shown in Figure 6 will accommodate bearings for 1/2-inch nominal diameter shafts; 3/8-inch shafts are made to fit 1/2-inch bearings by means of collar bushings. The ball bearings used in the bearing brackets and other parts usually are hand lubricated.

Figure 7 illustrates the special hardware necessary for use with mockup components. The square-head T-slot bolt is designed to fit the slots of pedestals and bearing brackets. A 1/4-inch 28-pitch thread is used. The shims are made in a variety of thicknesses up to one-half inch for supporting bearing brackets and other uses; the holes provide passage for bolts. Also shown are examples of clamp-blocks and dogs for mounting items that cannot be held by T-slot bolts.

Electronic Mockup Components

The success of the mechanical mockup components stimulated the development of electronic mockup components for use in electromechanical system mockups. To save engineering on system mockups, the development of standardized electronic units was justified. Such apparatus can be serviced by technicians and stocked in quantity so that failures will not delay experimental work on the mockup system. After successful system operation is obtained, the electronic-mockup-component units (abbreviated *EMC* units) can be replaced with prototype product units of the same over-all performance, but vastly simplified and diminished in weight and size.

The *EMC* units are classified as follows:

1. Cathode followers, Figure 8 part *a*.
2. Amplifiers, Figure 8 part *b*.
3. Output stages, Figure 9 part *a*.
4. Demodulators, Figure 9 part *b*.
5. Power supplies, not illustrated.

A cathode follower frequently is required for measurements and occasionally for isolation of networks. The *EMC* cathode follower is shown in Figure 8 part *a*. This cathode follower has a single-ended input and a single-ended output. Two stages are used to permit zero adjustment of the output signal without changing the input impedance.

The *EMC* amplifier, Figure 8 part *b*, is designed to sum six single-ended (or three push-pull) signals, phase invert, amplify, and transform impedance level. Figure 10*a* is a simplified circuit showing the principles of operation. The frequency response, shown by Figure 11, is flat in the range of interest for electromechanical system operation. The gain is adjusted by a control switch in discrete steps (spaced approximately in a logarithmic series) from a minimum gain of unity to a maximum gain of 40. The amplifier uses an inverse feed-back arrangement to accomplish the summation and the gain is varied by changing the feed-back ratio. To compensate for level changes in power-supply voltages and push-pull input signals, a tube has been incorporated to measure output level variations and apply corrections to the cathode of the second amplifier tube. A cathode-follower output tube is used. The input impedance is 1.2 megohms per input terminal; the output is push-pull with an impedance of 20,000 ohms over-all. Plus and minus voltages with respect to ground must be supplied to the amplifier; these are required because of the resistance coupling used between stages which makes response possible at zero frequency. The amplifier is used wherever voltage amplification, signal addition (or subtraction), signal inversion, or frequency-sensitive amplifiers are needed in system mockups. Circuits which typify its use with networks of specified frequency characteristics are shown in Figure 10*b*. The circuits correspond to the conventional lag and lead networks.[4,5]

An output stage, Figure 9 part *a*, is used to translate voltage signals into push-pull current signals for operation of small field-controlled servomotors and the like. The *EMC* output stage uses two beam-power tubes, type *6L6*, to provide a push-pull output; push-pull input signals must be supplied.

In electromechanical system work it is often necessary to convert self-synchronized signals, or suppressed carrier signals, back to their fundamental form. This is accomplished by demodulation in which a carrier or reference signal is supplied in addition to the suppressed carrier signal. The *EMC* demodulator is shown in

Figure 10 (left)

(*a*)—Simplified schematic *EMC* amplifier
(*b*)—*EMC* amplifier used to form lag and lead networks

Figure 11. Frequency response of EMC amplifier

Figure 9 part *b*. The single-ended input signal is amplified and supplied through a signal transformer to the full-wave detector tubes. The output may be either push-pull or single-ended.

To supply the plus and minus voltages required for the electronic units, regulated low-impedance power supplies are used. The plus and minus voltages most frequently used are ±200 to ±300 volts. One supply is used for the positive voltage and a second supply appropriately grounded is used for the negative voltage. Power supplies are rated for 240 milliamperes at 300 volts with a ripple of less than one millivolt rms. The source impedance is a function of frequency, but never exceeds 25 ohms and generally is much lower. The voltage is adjustable over the range of 200 to 350 volts.

Generally, a conventional unregulated power supply is used for the *EMC* output stage.

Connections are made to all electronic components by means of screw-type terminals. In a mockup the units generally are fastened to a plywood panel and the proper interconnections are made by push-back wire. When a large number of wires join a single terminal, a piece of bus wire is screwed to the terminal and the wires soldered to the bus wire. Much thought has been given to the possibility of using plug connectors and racks with only the signal terminals exposed, but this has not been undertaken because it would reduce the flexibility of unit application.

It will be noted that the *EMC* units comprise nothing new; they are of conventional design. What is new, perhaps, is the idea of having such units available in quantity. The engineer then may construct complex circuits using as fundamental elements these units rather than the separate circuit elements.

Mockup Component Problems

Mockup components have associated with them certain problems. There is a tendency to expand the line of standard parts to include items infrequently used. The basic principle underlying the mockup component idea is to have standardized, simple parts that can be put together quickly in a multitude of ways to serve a maximum number of uses. It is necessary to consider this principle before a new component is added to the standardized line. Another problem arises when, after a component is adopted as standard, a proposal is made to replace it with a part of superior design. The choices are

1. Adopt the new part and scrap the old one.
2. Adopt the new part and retain the old one.
3. Do not adopt the new part.

Generally, for the sake of economy, decision 2 or 3 is made. If decision 2 is made, an extra item is added to the line. If decision 3 is made no progress results.

In a large organization there may arise the problem of enforcing standardization. Engineers are essentially individualists and prefer to use their own ideas. Not infrequently some one will design and have built his own line of parts without consulting others. This is serious if company-wide exchange of parts is desired.

Conclusion

The mechanical and electronic mockup components have great utility in laboratories where electromechanical systems are developed. Once the initial investment has been made, complex systems may be mocked up rapidly at small cost. The components save much engineering time by making it possible for technicians to service and maintain system units. A considerable reduction in time for mockup construction is achieved by having available a stock of parts. This eliminates the repetitious designing and building of parts with substantially similar function for each mockup. When a mockup has served its purpose, it may be disassembled and the parts returned to stock for subsequent use.

Discussion

Robert F. Garbarini (Sperry Gyroscope Company, Great Neck, N. Y.): The laboratory aids for electromechanical system development which are described in the paper of Newton and White had their beginning in the computer engineering department of the Sperry Gyroscope Company. Prior to 1942, mockups of new devices were laid out on the drafting board, the parts sketched and manufactured. Since parts such as shafts, bearing blocks, and motor mounts were not designed for general use, they would be scrapped after the tests were

complete. Realizing the handicaps and wastes of such a procedure, and requiring more rapid solutions to problems, some engineers began to make their own stocks of useful parts. These soon proved inadequate in a laboratory that was doing an increasing amount of development work, because there was no standardization of parts and often not enough parts. The outcome of this was a systematic set of mockup components. Now, shafting comes by the yard, it has flats for set screws if required and has one standard diameter. A variety of adapters are available so that almost any gear which may be available in stock can be used.

Advantages

There are three important advantages of these laboratory aids which make them of value to the company, to the engineer, and to the customer who is paying for the development:

1. They make available a saving of time in both the shop and the laboratory where the mockup must undergo numerous tests and changes.

2. They make available a financial saving because of the saving in time and the continued usefulness of the parts.

3. By far the most important advantage is that uncertain devices or entire instruments may be tested before design layouts have progressed too far. It can prove embarrassing to an engineer to find that he has underestimated the required size of motor and does not have enough room for a larger one. These circumstances come about when production motors are available which are on the border line of having sufficient torque. Usually the next size motor is too large so that either a new motor must be developed or a chance must be taken with the smaller one.

Typical Applications

These laboratory aids are not the only ones that are used in instrumentation. The aids are used in conjunction with component such as multipliers, dividers, integrators, vector resolvers, and optical elements for mocking up a variety of instruments.

Data Systems. A complete electromechanical data system can be mocked up in a matter of a half day. In this case the transmitter synchro mechanism could be driven by a Scotch yoke mechanism which would provide a sinusoidal input. The amplitude can be varied by means of a screw driver adjustment, and the frequency changed by adjusting the speed of the angular drive motor of the Scotch yoke. The data receiver synchro mechanism is positioned by an amplifier-controlled servomotor and gearing. With the flexibility afforded by the laboratory aids, it is easy to change gear ratios, inertia, viscous damping, friction and backlash.

Thus, it is possible to study the frequency response of the system with different parameters.

Computing Circuits. A very important application of the laboratory aids is in the development of complicated electromechanical computing instruments which have to meet severe specifications as to weight, size, and accuracy. Such a computing instrument may consist of several servomotors and any number of mechanical computing elements such as adding differentials, multipliers, integrators, and polar converters, all connected in closed loops. Since allowable size determines scale factors, which in turn determine the errors caused by backlash and machining inaccuracies, it is quite difficult to determine by analysis just what the probable error of an instrument will be. This is particularly the case under dynamic conditions because the sensitivity of the servomotors often depends on how much backlash is present. If the backlash is decreased, the servomotor performance can be improved.

If the new instrument is complex, and there are no previous instruments of similar functions available for obtaining data, it not only is desirable but often necessary to build a working mockup. The experience obtained in studying and testing the mockup along with careful analysis, provides sufficient data for preparing sound proposals and design information.

R. S. Edwards (Sperry Gyroscope Company, Inc., Garden City, N. Y.): The paper of G. C. Newton and W. T. White presents a new type of tool for use in engineering laboratories involved in the development of electromechanical devices. The mockup components described in the paper have been used quite widely in several of the laboratories of the engineering department of the Sperry Gyroscope Company, Inc.

The widest use of these components has been in the system study work and preliminary test work of complicated electromechanical systems such as gun-sight computers, antiaircraft computers, and bombsights.

Most apparatus of this type involves the use of servomechanisms which often become quite complicated. A method of servomechanism analysis that is widely used at the present time is the sinusoidal input, frequency response method which has been discussed by G. S. Brown, A. C. Hall, H. Harris, and others. This method lends itself very well to the experimental approach and the experimental approach in turn is easily carried out with the aid of the mockup technique described by White.

The frequency response method of servomechanism analysis involves the determination of transfer loci or input to output ratios and phase angles as a function of frequency for the various components making up the servomechanism loop. Since servomotors and signal devices are often electromechanical devices the mockup components described by White are valuable for performing the necessary tests. Plates and brackets are available for holding the units properly and any necessary gearing is easy to install. The electronic mockup components ease the problem of measurement. The generation of proper input signals is also eased by the use of both mechanical and electronic mockup components. Although transfer functions can usually be determined analytically, it is always wise to check the results experimentally and often the experimental values are more accurate. When the transfer loci of the components of the servomechanism loop are determined experimentally, the subsequent analysis of the loop as a whole is much simplified.

The problem of experimental verification of the results of the loop analysis is also much easier if a laboratory well stocked with mockup components is available.

Once the general form of the servomechanism loop is determined the mockup is valuable for determining the particular values of components to be used. Allowable tolerance of components that determine gain of servoamplifiers and time constants and proportionality factors of stabilizing networks may be determined quite readily by experimental testing.

Present day equipments of the sort mentioned above often have complicated servomechanism systems with multiple loops. These multiple loops usually occur when there are one or more servomechanism loops that are entirely within another loop, or as sometimes occurs, two separate servomechanism loops have mutually interacting terms. The analysis of such servo systems is a rather tedious and difficult job particularly if conditions are to exist in each of the servo loops which will give optimum performance of the over-all system. The use of mockup components allows a practical experimental approach to this problem. When properly organized, the experimental data can usually be obtained and correlated in less time than an analytical approach can be made.

There are other aspects of electromechanical systems which cannot wait for pilot model production. One of these deals with the co-ordination and time constants of the operator of the equipment since in many cases the operator is included in the over-all servomechanism loop where he is required to perform tracking or similar operations. The use of a flexible electromechanical mockup permits a wide experimental investigation of this problem.

As pointed out by White, the use of mockup components in servo and other problems is not in itself an analytical tool but rather a time-saving device whereby the necessary answers can be obtained long before a unit reaches the pilot model stage.

The speed with which a mockup can be made and proved is of great importance in the initial examination of a problem. Most engineers dealing with complicated electromechanical equipment, having made an analysis of the problem, have been confronted with the question, "Yes, I understand all you have on paper, but will it work?" A working mockup which can be built in a short time is a decided asset in such cases.

Donald L. Herr (Control Instrument Company, Inc., Brooklyn, N. Y.): White's methods of utilizing relatively fixed components for assembly in laboratory mockups of servomechanisms is ingenious and no doubt efficient in programs of a highly related nature and where such laboratory mockups can be relied upon and utilized safely in the development of a complete servomechanism. We, of the Control Instrument Company, have developed and are using a method of servomechanism synthesis to which White's laboratory mockup technique in some cases lends itself quite well. Such cases are where certain components of the entire servomechanism are relatively fixed from the beginning of the problem and it is desired to rapidly investigate the effects upon performance of other variable components introduced into the system. It is believed that the Control

Instrument Company synthesis method may be found fundamentally of interest and value.

It is necessary to go back to some fundamental considerations. We cannot, it seems to me, place great emphasis upon structural or configurational difference in servomechanisms as a basis for differentiating between servomechanisms. Actually, of course, the structural configuration of a servomechanism is chosen because of the engineering advantages resulting from the use of available components which appear in those arrangements, whereas, mathematically, servomechanisms fundamentally differ only as they differ in their over-all transfer functions. For any given transfer function, there is an infinite variety of structural configurations which will give rise to that same transfer function. It is, however, the over-all transfer function which specifies the accuracy and stability of the servomechanism, regardless of how it is physically obtained as an engineering structure. So rather than continue to speak about the properties of each individual case of actual servomechanisms, which leads us into many detailed considerations characteristic largely and only of each individual physical servomechanism, a fundamental method of synthesis is to start with the loop transfer function, having the properties which satisfy the stability and accuracy requirements of a particular application, and then attempt to synthesize the servomechanism to that loop gain function and its corresponding system response function. The method is as follows.

Mathematically, the loop gain functions proceed from the simplest type involving only a constant divided by some positive power of the periodicity to those involving a constant times a ratio of one polynomial in real frequency to another, in which the roots of numerator and denominator may or may not be placed in evidence. Loop transfer functions, mathematically, are more complex the more terms or roots there are in the numerator and denominator functions. We may exhaustively examine all of the properties of such ratios of functions for each successive case of increasing complexity. In doing so, we start out on the basis that we desire to synthesize a system having a certain degree of stability, as indicated by its maximum value of system response function, and fulfilling a certain accuracy requirement, which establishes the value of the constant multiplier of the ratio of polynomials. These may be called the steady-state stability and accuracy requirements. In any particular application, the steady-state stability and accuracy requirements may be sufficient to form the basis of our synthesis. However, in certain applications, the percentage overshoot and time of build-up of the transient response may be the determining factor, so long as the system is characterized as stable.

If we now view the servomechanism as a low-pass filter, we can somewhat arbitrarily say that we desire to synthesize those servomechanisms which meet either the steady-state stability and accuracy requirements or which meet the transient response requirements with stability and that, in either case, we desire our servomechanism, or low-pass filter, to be of the "minimum band width type". In other words, we desire to synthesize that servomechanism which, when viewed as a low-pass filter, has the narrowest pass band consistent with fulfilling whatever stability and accuracy requirements must be met in a particular situation.

On this basis we have found it possible to take successively more complex, physically realizable transfer functions and, on a normalized frequency basis, elicit the values of the design frequencies in the loop transfer function around which the servomechanism is synthesized. When this has been done a servomechanism results which is of the "minimum band width type" and which meets whatever accuracy and stability requirements are specified.

The mass or structure that is controlled is itself, of course, an element in the servomechanism and, very often, is "something which is handed to us" and which cannot be changed but which must be controlled by the closed loop system we build around it. It is necessary to obtain the frequency response characteristic, in amplitude and phase, of any such fixed elements, remove this transfer function from the idealized transfer function which we have chosen from a tabular array as being the simplest which satisfies the prescribed accuracy and stability requirements on a "minimum band width" basis, and then the residual problem of design becomes that of synthesizing the remainder of the idealized transfer function. At this point we have available the infinite number of possible circuit configurations to synthesize this portion of the chosen over-all transfer function.

By use of the mockup technique, similar to that described by White, certain of the physical components in the remaining portion of the idealized transfer function are of fairly universal application such as modulators, demodulators, filters, stabilizing networks. Only the appropriate gain levels need be established and a residual stabilizing or equalizing network be synthesized.

In conclusion we should like to point out that this method of synthesis places in glaring evidence the very close interconnection between the transient overshoot and time of build-up, on the one hand, and the degree of stability of the system, as indicated by the maximum value of steady-state θ_o/θ_i, and the gain level or steady-state accuracy factor, on the other hand

The Economies of Using Capacitors in Amounts to Require Automatic Switching

J. W. BUTLER
FELLOW AIEE

AT PRESENT price levels, capacitors generally can be justified in quantities considerably in excess of what electric systems can permit to be connected permanently. The average price of kilovars today, as supplied by capacitors, is one quarter of the price of 15 years ago, while other system equipment has increased in price 25 to 30 per cent during the same period. Obviously this lower price level greatly increases the economic sphere of application. It is believed that, if the economics of capacitors at their present price level are to be realized fully, switching procedures should be adopted more widely to allow for the use of larger quantities than the system can accommodate in permanently connected equipments.

The availability in general, and during these times in particular, of reliable factory assembled capacitor equipments complete with circuit breaker and automatic control makes this form of kilovar supply a full-grown economic tool of the distribution and subtransmission engineer. It allows him to design in more detail toward the desirable objective of having at the dispatcher's complete control the basic system kilovar generation, which, as will be shown, makes for maximum system economies.

On the Economic Operating Power Factor

Trite as it may be, the question, "How much of my high-priced system investment should be used to generate and transmit and distribute 10-dollar kilovars?" has not been answered very thoroughly by system planning and operating engineers. At the time of peak load, system capacity has its highest value, so it follows that minimum kilovar transmission generally should prevail at this time. The problem is to determine how many kilovars should be generated at this time by the powerhouse and transmitted to the load, and how many kilovars should be supplied in the load areas. Two approaches that may be taken to help answer this question are offered.

Thermal Limited Equipment

Allocate Kilovar Usage of System Capacity on the Basis of Its Use of System Thermal Capacity. The heating in a piece of electric equipment carrying a load, kilovolt-amperes, is proportional to (kilovolt-amperes)^2. The heating caused by the kilovar in this kilovolt-ampere load is proportional to (kilovars)^2, and that caused by the kilowatt load is proportional to (kilowatt)^2. This follows from the fundamental relation.

$$kva^2 = kw^2 + kvar^2$$

Therefore, the per unit heating, or thermal capacity used by kilovars is equal to

$$\frac{kvar^2}{kva^2} = \sin^2\theta \qquad (1)$$

and, as the per unit kilovar flowing is equal to

$$\frac{kvar}{kva} = \sin\theta \qquad (2)$$

Paper 47-55, recommended by the AIEE committee on automatic stations for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 1, 1946; made available for printing December 26, 1946.

J. W. Butler is with the capacitor section of the General Electric Company, Pittsfield, Mass.

it follows where equation 1 is divided by equation 2, that the per unit thermal capacity used *per kilovar* of load is equal to sin θ.

If S equals value of system in question in dollars per kilovolt-ampere and C equals cost of capacitors in dollars per kilovar, the economic operating condition, exists when

$$S(\sin\theta) = C \qquad (3)$$

That is, when the dollars per kilovar charged for use of system thermal capacity equal the cost of load area kilovar generation, the economical value of kilovars then are flowing through the system.

Figure 1. System operating power factor at which investment usage by kilovars equals the cost of capacitors

A—Based on thermal capacity usage by kilovars

B—Based on kilowatt capacity usage by kilovars

Figure 2. Fraction of total voltage drop in various conductors caused by kilovars

From equation 3 it follows that

$$\cos\theta = \sqrt{1-(C/S)^2}^{*} \qquad (4)$$

= the economic operating power factor by definition, consistent with the assumptions

This relation is plotted in Figure 1 as curve *A*.

Allocate Kilovar Usage of System Capacity on Basis of Its Use of System Kilowatt Capacity. Consider a system or portion of a system operating at its kilovolt-ampere rating at any given power factor. As a system is designed and operated primarily for the purpose of supplying kilowatts to the load requirements, it appears logical to allocate against kilovars, a usage of system capacity according to the relation,

kva − kw = system kilowatts capacity used by kilovars, where kilovolts-amperes and kilowatts are absolute values

If the cost of the system in question is S dollars per kilowatt, then it follows that

$$\frac{S(\text{kva}-\text{kw})}{\text{kvar}} = \text{dollars per kilovars chargeable for their usage of the system investment} \qquad (5)$$

When this charge for use of investment is equal to the cost of supplying kilovars in the load area, it will be said, by definition, that the system is operating at its economic power factor.

Equating equation 5 to C, the cost per kilovar when supplied in the load area, dividing through by the kilovolt-ampere, and rearranging yields

$$\frac{1-\cos\theta}{\sin\theta} = C/S \qquad (6)$$

solving

$$\cos\theta = \frac{1-(C/S)^2}{1+(C/S)^2} = \text{economic operating power factor, by definition, consistent with the assumptions} \qquad (7)$$

This relation is plotted in Figure 1 as curve *B*.

The results of this analysis are reasonable when applied where capacity really is needed, as the effects of kilovars on voltage drop and losses—both important—have been neglected. The results, however, are worthy of further consideration.

Numerical Application. Consider a transmission line over which kilovars are being transported from a generating plant, where kilovars can be produced relatively inexpensively. Each kilovar being transported is stepped up through a high voltage substation. It then is stepped down possibly three times before it gets to the load. These substations conservatively cost an average of $15 per kilovolt-ampere, which gives a figure of $60 per kilovolt-ampere for substation investment through which these kilovars flow during peak load in getting to their destination. Kilovars can be supplied in the load area by capacitors for $10 per kilovar. Hence, referring to Figure 1, curve *B* (the more conservative of the two curves), for a C/S of 0.167 (10/60), it is seen that the power factor should be 0.95 to make the investment charge equal the capacitor cost.

It appears reasonable to say, therefore, that, where substation capacity really is needed, its use for supporting the transportation of kilovars cannot be justified below some value on the order of 95 per cent power factor. These figures indicate that a much broader use of load area kilovar supply can be justified than now is practiced. The trend, however, is definitely toward higher system operating power factors, as indicated to a certain extent by the industry in adopting an 0.85 power factor turbine generator in place of the previous 0.8 power factor unit in general use.

Figure 3. Energy loss reduction by power factor improvement in terms of total system I^2R losses

L_p = kilowatt current loss factor
L_q = kilovar current loss factor

Where Voltage Drop Is Limiting Factor

In system elements where voltage drop is the limiting factor—such as overhead lines—it appears logical to charge kilowatts and kilovars for use of the investment for that particular equipment on the basis of the portion of the voltage drop which they produce. With this assumption, a reasonably direct analysis can be made for determining overhead line investment usage by kilovars.

An approximate but convenient expression for voltage drop is

$$V_d = I(R\cos\theta + X\sin\theta) \qquad (8)$$

I = amperes
R = resistance
X = reactance
θ = power factor angle

Figure 4. Approximate price in dollars per kilovar versus equipment rating with power circuit breaker switching device

* This relation was first derived in an unpublished manuscript by L. R. Janes, Public Service Company of Northern Illinois by an entirely different approach using differential calculus.

The fraction of the total drop caused by kilovar current is

$$V_q = \frac{N \sin \theta}{\cos \theta + N \sin \theta} = \frac{N \tan \theta}{1 + N \tan \theta} \tag{9}$$

Equation 9 is plotted in Figure 2.

Numerical Application. Consider an overhead line with $X/R=3$. From Figure 2 it is seen that one half the voltage drop is caused by kilovars at 95 per cent power factor. In other words, one half the line investment should be charged against kilovar usage of the line at the relatively high power factor of 95 per cent. Another line having $X/R=2$ will show that one half the investment is chargeable at 90 per cent power factor.

From such fundamental consideration, one readily may determine whether it is economical to use the line to transport kilovars from a relatively inexpensive source to the load, or to generate them near the load with supplementary kilovar generation, such as capacitors.

Energy Losses Due to Kilovar Transportation

Another closely related and important angle to the kilovar supply problem is that of energy loss reduction. It is not uncommon to find that the total kilowatt-hour loss in a system closely approximates the residential kilowatt-hour sales. All of these losses obviously are not retrievable, as power current losses and transformer iron losses are not necessarily affected by kilovar flow. But certain sizable loss reductions can be affected by reducing kilovar transportation, as indicated by the following analysis.

The maximum loss reduction is obtained with unswitched capacitors when only the average kilovar requirement is supplied. This, however, obviously is not the maximum obtainable reduction, because in supplying the average requirement the capacitors must be supplying an excess of kilovars during the light load periods which cause losses. Switching allows more capacitors to be used at peak load and then removes them at light load. The economies of this measure are determined to a certain extent by the credit given for the increased kilowatt capacity saving made available at time of peak, commonly called "demand saving".

One approach to determining the energy savings through load area kilovar supply is offered here. The per unit annual energy loss due to kilowatts is

$$W_p = \mathrm{kw}^2 k_1 L_p \tag{10}$$

Figure 5. Automatic single-step voltage control for capacitor switching

and the per unit annual energy loss due to kilovars is

$$W_q = \mathrm{kvar}^2 k^2 L_q \tag{11}$$

where

L_p = annual loss factor of kilowatts
L_q = annual loss factor of kilovars
Kw = per unit annual system kilowatt peak load
Kvar = per unit annual system kilovar peak load
k_1 = equivalent per unit resistance through which kilowatts flow
k_2 = Equivalent per unit resistance through which kilovars flow

If it is assumed that the kilovars that leave generators take the same general paths as the kilowatts, $k_1=k_2=k$, then since $W_P+W_Q=1.0=$ total I^2R system losses, add equations 10 and 11 and equate to 1.0 and solve for equivalent per unit resistance, to get

$$k = (K_w^2 L_p + \mathrm{kvar}^2 L_q) \tag{12}$$

Substitute equation 12 back in equation 11 and simplify

$$W_Q = \frac{1}{\dfrac{L_p}{L_q}\dfrac{1}{\tan^2 \theta} + 1} \tag{13}$$

$\tan \theta = \dfrac{\mathrm{kvar}}{\mathrm{kw}}$ and θ = power factor angle at time of system peak load

From equation 13 the per unit system I^2R annual energy losses attributable to kilovars can be determined readily from the peak load power factor angle and the ratio of the active and reactive loss factors.

It readily can be shown that the ratio $R=L_p/L_q$ should lie between 0.6 and 0.9 for actual system load patterns. Using these two limits for the loss factor ratio, the curves in Figure 3 are plotted.

Numerical Application

The following figures apply to an actual system:

Peak load—87 000 kw at 0.85 power factor.

Annual I^2R energy losses—40,000,000 kilowatt-hours

Referring to Figure 3, by improving from 0.85 to 0.90 power factor, approximately ten per cent of the annual I^2R losses are saved. This is assuming the ratio of the active and reactive loss factors remains constant, which would be the case only if the kilovar supply were controlled in infinitely fine steps, so as not to alter the kilovar load pattern and thus maintain the loss factor. If capacitors were being used for this kilovar supply, some would be applied unswitched and some would be switched in finite steps, hence the kilovar loss factor actually would reduce and the ratio of loss factors would increase, which is in the direction of a larger energy saving. Therefore, it appears reasonable to use the 10-per-cent saving figure in going from 0.85 to 0.90 power factor. This represents a 4 million kilowatt-hour saving, in this case, and at four mills, an annual saving of $16,000 is realized.

To improve the power factor from 0.85 to 0.90, and realize these savings 12,000 kvars would need to be supplied near the load. If capacitors were used at $10 per kilovar installed, and a per unit

annual carrying charge of 12 $^1/_2$ per cent applied, the carrying charge would be $15,000 per year. Under these conditions the capacitors are justified strictly on loss savings. This is not unreasonable, as a few large scale installations of this nature actually have been made and proved in on loss savings alone. Assuming the assumptions were sufficiently off to introduce a 50 per cent error, it still indicates that load area kilovar supply could be half paid for by loss savings—a factor which often is ignored.

Analyses need to be made for each individual system for accurate figures, but certainly these savings are important and should not be overlooked in the quest for lower cost power.

Figure 6 (left). Three-step automatic kilovar control for capacitor switching

Figure 7 (right). Auto-Switch capacitor equipment, rated 180 kva, 2,400–4,160Y volt, 3 phase, 60 cycle, complete with capacitor units, fuses, and oil switch with automatic control and potential transformer

On Establishing a Practical Minimum Load Power Factor

The requirement for switching capacitors develops when the kilovar supply at time of peak load exceeds the desirable kilovar supply at time of minimum load. The kilovars to be switched are equal to the difference between the peak load and light load requirements. Therefore, to be conservative (on the low side) on estimates of the switched capacitors, the unswitched requirements should be as great as practicable. The amount of unswitched capacitors a system can accommodate generally is governed by two conditions.

Voltage Considerations

When all links of a system are operated at unity power factor during light load period, the system is operating with what is termed a *flat voltage*. Under this condition there is no voltage rise along any line such as a circuit or feeder. This is an extremely acceptable operating condition. In fact, it is not uncommon for certain feeders in a system to operate during light load with a rising voltage gradient due to the amount of permanently-connected capacitors. For purposes of this discussion, unity power factor or flat voltage operation as an average in the system will be taken as the ultimate for light load operation. Few operating companies have attained this goal in their kilovar supply program.

Stability Considerations

It generally is considered by operating engineers that unity power factor operation of generators at light load is acceptable from the system stability standpoint. Some feel this is going a bit too far, while others, when adequate voltage regulators are used under certain conditions, will allow their generators to operate slightly underexcited. This subject is a complete one in itself and has been treated elsewhere,[1,2] but for the purpose at hand, suffice it to say that unity power factor generator operation at light system load will be taken as the limiting condition in the application of uncontrolled kilovar supply.

The Necessity of Switching Capacitors

Operating data of systems indicate the full load kilovar requirement to be on the order of three times the light load requirement. The first part of this analysis established that peak load power factors of approximately 95 per cent are in the economic realms of possibility. Approximately one kilovar requirement accompanies every kilowatt of load, and, as at 95 per cent power factor the kilovars equal 1/3 of the kilowatts, it follows that a value of regulated kilovars that is economically feasible is one approximating the light load requirement, or about one third of the total. If these kilovars are to be supplied by capacitors, they must be controlled by switching and if the kilovar supply is to follow the load pattern requirement and keep within circuit loading and voltage requirements, automatic switching is the answer. If these kilovars are supplied by synchronous condensers, the automatic voltage regulator will control them in accordance with requirements.

Where Do Capacitors and Where Do Synchronous Condensers Fit Into This Picture?

This additional kilovar generating capacity, over and above the amount that can be installed on an unswitched capacitor basis, can be divided roughly into two categories.

1. Kilovar generating capacity is characterized by a need for constant and finely controlled adjustment with changing system conditions. The range of this adjustment will include, not only going to zero output but also to reverse to take care of light load or loss of load conditions. It also involves the requirement that the kilovar generator deliver sudden increases in kilovar output as required by system conditions, such as loss of transmission lines. In general, these broad requirements are associated with

kilovar generators associated with major transmission and therefore appear in fairly large unit blocks. The foregoing is a rough description of the system requirement that tends to indicate the synchronous condenser as the proper kilovar generator.

2. There are many locations on the average power system, generally in the distribution and subtransmission areas, where kilovar generation under load conditions is justifiable to a point where it often will seem embarrassing from a system operating standpoint under light load or loss of load conditions if the generation is maintained. These locations generally tend to indicate the need for kilovar generators in smaller blocks than when associated with the major transmission, and, therefore, still tend to fall in the capacitor class. Of course, even here, if synchronous condensers are available on a major transmission, they will be able in some degree to compensate for the overgeneration of kilovar by the capacitors under light load conditions and thus tend to allow more unswitched capacitors.

The type of kilovar supply chosen is based, for the latter category, on first cost, and such items as availability, flexibility, and maintenance, all need to be factored into the broad economic picture. Based on installed cost only, capacitors are favored in banks up to approximately 15,000 kilovar, and their availability at present is materially better due to general manufacturing conditions. Also, as a 10,000 or 15,000 kilovar capacitor, as contrasted with the condenser, initially or later can be broken down into smaller units and located near the kilovar requirement in case of changed conditions, the flexibility factor is in its favor. Even if a consenser is to be used later, the availability and flexibility factor may justify the capacitory on a temporary basis.

Fineness of voltage control, as offered by the condenser, may be advantageous in many instances. The capacitor, however, does not provide what would be called *coarse* voltage control for many applications. For example, a 15,000 kilovar bank probably would be located at a point in a system which would supply a short circuit of approximately 250,000 kva. Hence, if the capacitor bank is switched in six 2,520-kva steps, each step would give a voltage change of only one per cent. This voltage change would be a maximum at the capacitor location and would diminish as the electrical distance from the bank is increased. Such an operating result would need to be considered and judged on its own merits for the individual case.

Cost of Switching Capacitors

There is a general misconception extant that switching capacitors is an expensive procedure. In the smaller equipments, the cost per kilovar can become relatively large, but in larger substation equipments, where the controlled banks are used, the cost is quite small. Good estimating figures[3] for switched equipments are given in Figure 4. Factory-built housed equipments without circuit breakers range from $5 per kilovar for the 5-kv class up to $6 per kilovar for the 15-kv class. When these figures are compared with those in Figure 4, the cost for switching readily is seen for the different sizes.

These prices do not include automatic control. Estimated prices for various types of control and different number of steps are given in Table I.

Table I. Approximate Price of Indoor Automatic Capacitor Control Equipments[3]

Number of Steps	Voltage	Current	Kilovar
1	$300	$300	$400
2	600		700
3	650		750
4	700		800
5	750		850

For outdoor enclosure add $75.

Figure 8. Capacitor installation totaling 15,120 kilovars

Made up of six large outdoor floating-neutral type equipments, throat connected, each rated: 2,520 kilovars, 13,800 volts, 3 phase, 60 cycles, each with built-in type *AM-15-250* Magne-blast circuit breaker electrically operated for automatic control

Typical Switching Equipments and Installations

Figures 5 to 8 illustrate a few equipments and show how they go together in a substation installation.

Conclusions

1. The basic load kilovar requirement of a system generally can be most economically supplied by capacitors.

2. The capacitor's reliability, cost, and flexibility have resulted in one of the most economic tools that is now available to the system planner and designer. And its availability due to favorable manufacturing conditions at present makes it attractive even on a temporary basis, where a condenser may be used later.

3. Capacitors generally are justified in the system design and operation pattern in such quantities as to require switching.

4. The cost of switching is so small it is not a deterrent or a controlling factor in an economic analysis, the main criticism being the system's ability to accommodate the stepped control as contrasted with the fine control a condenser gives with an automatic generator voltage regulator.

Discussion

W. R. Brownlee (Commonwealth and Southern Corporation, Jackson, Mich.): It is believed that the advantages of switched capacitors as a useful tool in system planning generally are recognized, and they justly are finding a place on power supply systems as a source of reactive power along with unswitched capacitors on distribution lines, synchronous condensers at strategic locations, and the synchronous generators themselves. Certain cautions must be observed in determining the "most economical power factor" of power supplied by the generating units.

In the case of some older plants and systems, which may have been planned and designed without proper regard to or sufficient knowledge of kilovar requirements, surprisingly high power factors at the generators may be justifiable. However, the enormous increase in generating capacity in recent years results in power supply systems with a substantial proportion of modern efficient generating units and associated equipment, with ample opportunity to take full account of kilovar requirements and to produce balanced designs. Accordingly, there should be no limitations in the kilowatt producing ability of these plants because of the necessity of supplying also the designed amount of kilovars. Therefore, any investment savings credited to the installation of switched capacitors must be confined to the transmission and subtransmission systems, usually extending no further than the low voltage distribution substation busses.

With the economical loading of transmission systems, substantial amounts of kilovars will be required at points other than the load centers. Certainly the kilovars required for the magnetizing current and I^2X loss of step-up transformers of generating plants can be supplied most economically by the generators, even if the respective kilovar production costs were equal. Substantial amounts of kilovars also will be required for the net reactive "loss" in a transmission line, and this is supplied more economically from the generating end. These and similar extra kilovar requirements may account for a generated power factor (including condensers and capacitors as "generators") as low as 80 per cent, with a power factor at the subtransmission stations of as high as 90 per cent. Thus the economical power factor at a typical generating station may be more nearly on the order of 85 to 88 per cent, rather than 95 per cent as advocated by the author.

The examples used to illustrate the curves and equations may be misleading, because they consider the *total* transmission system investment rather than the *incremental* investment which might be required to transmit certain portions of the system kilovar supply. For example, the cost of transformers themselves may increase about as the square root of the kilovolt-amperes rather than the first power, and other items of substation expense may not be increased at all by moderate increases in substation kilovolt-amperes. Similar reasoning applies to transmission lines.

T. W. Schroeder (United Light and Railways Service Company, Davenport, Iowa): It is interesting to note from Butler's analyses and examples that the economic system power factor is creeping ever nearer unity, as the ratio of system investment per kilowatt to kilovar generation cost per kilovar increases. The fact that the cost of automatic switching equipment does not add greatly to the price per kilovar of capacitor banks in reasonable sizes certainly should further the use of comparatively large blocks of switched capacitors on electric utility systems generally now and in the future.

The present high value of the system investment to kilovar generation cost ratio leads to two conclusions, namely,

1. That a large share of the kilovar requirements of large commercial and industrial loads should be supplied near the load.

2. That the comparative cost of furnishing the kilovar component of these loads is small.

These conclusions lead to the reasonableness of the view that the utility rather than its commercial or industrial customers, is in the best position to supply the load kilovars, because in general

1. The utility can supply the kilovar requirements at lowest cost, from an over-all utility–customer viewpoint, because it can do the job with larger blocks of kilovar generation and fewer total kilovars by reason of diversity of load requirements.

2. The utility logically should have control of the system kilovar generation, particularly as economics dictate the use of greater quantities of controlled kilovar generation, such as switched capacitors.

Exceptions to this reasoning will occur, of course, such as cases where the customer requires the kilovar generation in his own plant for benefit to his own system, and where large amounts of synchronous drive equipment are used.

On the basis of the foregoing reasoning, it also develops that the utility's charge to customers for kilovars will be small, as compared with the kilowatt charge. It may be small enough to justify its complete omission from the rate structures in the interests of simplicity—thus doing away entirely with the cumbersome appendage of the "power factor clause." This actually has come about in the case of one of the United Light and Railways' Systems' properties.

Energy Losses Due to Kilovar Transportation

In substantiation of Butler's discussion pointing out that large scale capacitor installations may be justified on the basis of energy loss reduction alone, an actual case may be cited.

System Data

1. System generation at peak load—130,000 kw

2. Power factor of generation at peak, without capacitors—82.4 per cent

3. Power factor of generation at peak with 27,540 kilovars of capacitors installed—94.0 per cent.

4. Calculated loss reduction at peak with 27,540 kilovars capacitors—1,275 kw.

5. Estimated installed cost of capacitors (10,260 kilovars in outdoor units on distribution circuits and 17,280 kilovars in substation banks)—$222,421.

6. Average annual load factor—approximately 50 per cent.

7. Estimated system equivalent hours (number of hours per year maximum load must prevail to give same losses as actual load—depends on shape of load curve)—2,800.

Assumptions

1. Energy production cost—$0.003 per kilowatt-hour.

2. Generating station investment—$165 per kilowatt on firm capacity.

3. Fixed charges on investment—12.5 per cent.

Calculation of Loss Savings and Comparison With Capacitor Investment

Annual Saving in System Losses	
2,800×1,275=3,570,000 kilowatt-hours at $0.003	$10,710
Demand Saving Due to Released Generating Capacity	
1,275×$165=$210,375 at 12.5 per cent	$26,297
Total gross annual savings	$37,007
Investment Charge on Capacitors	
$222,421 at 12.5 per cent	27,802
Net Annual Savings	$ 9,305

It will be noted that an evaluation of the release of generating plant capacity was included on this analysis.

Using Figure 3 of Butler's paper, improving the power factor from 0.824 to 0.94 results in a reduction of energy loss of

0.25 per unit for $L_p/L_q=0.6$
0.22 per unit f r $L_p/L_q=0.9$

The actual calculated loss reduction at peak for the case cited here is from 4,655 kw to 3,380 kw, or 0.274 per unit.

Minimum Load Power Factor

As an indication of the possibilities of high power factor system operation the St. Joseph Light and Power Company, St. Joseph, Mo., may be cited as an example. This is an urban type system of peak load (1946) of approximately 30,000 kw. In recent years, to make maximum use of system capacity for kilowatt transportation, unswitched capacitors have been installed on 4-kv and 12-kv busses and feeders in amounts totaling approximately 10,000 kilovars. Heavy load power factor varies from 0.87 to 0.95.

Two generators, a 7,500-kw 0.7-power-factor and a 10,000-kw 0.8-power-factor machine, are normally in operation during light load. Both machines feed a common 4-kv bus. Excitation is provided from an exciter bus supplied by a dual-driven motor-generator set. The exciter bus voltage is controlled by a direct-acting type generator voltage regulator.

Minimum load generator operation has been underexcited slightly and at present is very near unity power factor to slightly overexcited. Minimum load is about 12,000 kw.

No particular difficulty has been experienced with this type of operation. Light load system voltage is controlled by reduction of generator bus voltage on a clock schedule. It is probable that future large

capacitor installations on the system will employ automatic switching equipment.

J. W. Butler: It has been the general rule with operating companies in the past to design a power station with boiler, feed water, and such facilities to enable the prime mover to deliver kilowatts equal to the kilovolt-ampere rating of the generator. Obviously, there have been some exceptions to this practice. In the general case, therefore, if the designed amount of kilowatts are to be obtained, some kilovars must be provided from auxiliary sources. The ability to increase the kilovar capability by increasing the hydrogen pressure in hydrogen-cooled generators is taken advantage of by some companies. These considerations obviously all should be factored in the individual problem. I believe Brownlee's discussion, wherein he referred to stations having "substantial proportion of modern efficient generating units and associated equipment, with ample opportunity to take full account of kilovar requirements and to produce balanced designs" concerned modern stations or possibly those still in the design stage. To this I very well agree. There are, however, a very large number of older stations wherein valuable designed kilowatt capacity is "bottled up" by kilovars. To these older stations, I do not believe the principle of "incremental costs" should be applied in the process of justifying or not justifying capacitors. If by removing said kilovars, additional kilowatts become immediately available, then the actual value of these kilowatts at present time rather than their incremental costs should determine the choice.

It is truly refreshing to see a representative of an operating company offer the philosophy outlined in the first part of Schroeder's discussion. And this writer feels it to be a definite forward step for a utility to abandon the so-called "power factor clause," as has been done by one of the United Light and Railways' properties.

It is gratifying to obtain actual system data regarding loss savings obtained through the application of capacitors and check them with a generalized approach. An explanation of Schroeder's use of Figure 3 of the paper may be in order.

As energy loss = peak loss $\times$ 8,760 $\times$ loss factor, the data in Figure 3 can be used to estimate peak kilowatts loss as well as annual energy loss. As outlined under "Numerical Application" of the energy loss savings section of the paper, the ratio of the loss factors (Lp/L_q) will actually increase when capacitors are applied, instead of remaining constant due to the change made in the kilovar pattern. Therefore, using the lower limit of the loss factor ratio ($Lp/L_q = 0.6$), as the "before" condition, and using the upper limit as the "after" condition, we obtain a peak loss saving of 0.28 per unit when improving power factor from 0.824 to 0.94. This is surprisingly close to the figure of 0.274 per unit actually calculated by Schroeder with detail system data.

The operating data of the St. Joseph Light and Power Company system should be useful. It substantiates the philosophy that light load power factors of around unity to be entirely practicable from the operating standpoint. And the value of capacitors required to bring the light load condition to approximate unity very closely checks that value given in the paper under the section "The Necessity of Switching Capacitors," namely, a value equal to approximately one third of the peak kilowatt load.

Testing Governor Performance on Electric Power Systems With Improved Instruments

J. E. ALLEN
MEMBER AIEE

W. B. HESS
NONMEMBER AIEE

FOR GOVERNORS to perform well it is essential that they possess certain operating characteristics at the time of installation and throughout their operating life. Heretofore such characteristics have been difficult to measure. This paper describes governor-testing methods and instruments, applicable to both steam and hydro units, which mark a distinct advance in the technique of governor testing.

Historical

When the governors were installed at the Safe Harbor hydroelectric plant, starting in 1931, they were tested under operating conditions by using the oscillograph to record instantaneous frequency without the inherent lag common to instruments employed up to that time.[1] The records, showing, among other things, frequency and gate opening as a function of time were analyzed subsequently by plotting simultaneous values of these two variables as functions of each other to secure diagrams* known as figures of Leaute.[2] These diagrams of frequency versus gate, recurring because of the governor's adjusting itself to each change of frequency, proved extremely valuable, first in detecting the imperfections in the governor operation, and later as a measure of characteristics desired in a governor. However, the hand plotting was so laborious and slow that it became highly desirable to develop an instrument which would accomplish automatically the same as an X-Y recorder; and thus it immediately would give the results in a manner similar to the familiar steam-engine indicator card diagrams. This requirement was met satisfactorily by an instrument completed in 1940. The equipment has been developed since to record diagrams of frequency as a function of kilowatt output of the generator. The usual strip chart records of frequency, gate-operating piston, and kilowatts as a function of time are recorded simultaneously with the same instrument.

Scope of Paper

The first part of this paper is intended to describe the mechanical and electrical features of a new frequency recorder, the essential element in the instrument for automatically plotting the diagrams of frequency versus operating piston, or frequency versus kilowatts. The equipment for recording kilowatts also is described. The second part of the paper describes the results obtained when using the instrument as an aid in the maintenance of governors and for measurement of their operating performance. Examples of card diagrams obtained under operating conditions will be given.

Results

The card diagrams of frequency versus operating piston and frequency versus kilowatts have proved to be the best means thus far devised for measuring over-all governor performance. The most important characteristics, such as sensitivity, dead band, speed droop, and regulation are readily apparent on these diagrams. Such factors as friction, lap, compensation, maladjustments, and so forth give characteristics readily recognized and evaluated by experience. The instrument has served as a valuable guide in detecting and correcting governor difficulties, because the results are immediately available.

Terms and Definitions

In the past considerable confusion has arisen from the fact that definitions pertaining to the subject of speed regulation and governing have not been standardized. There is a joint committee of the American Society of Mechanical Engineers and the AIEE now engaged in this task, and consequently for this paper it is necessary to make some arbitrary definitions solely for the purpose of describing the results obtained by test.

Sensitivity and Dead Band

Dead band is considered to be that band of frequency variation in which there is no corresponding movement of the operating piston. In actual operation the governor is subjected to a complex succession of frequency variations during which the governor continuously is adjusting itself. Consequently it becomes difficult in tests of this kind to distinguish the dead band as defined. Furthermore the unavoidable lag in the gates or valves while attempting to follow the frequency gives the diagram a width over and above that which would be caused by the dead band alone. The term sensitivity as used in this paper will refer to the total width of the diagram even though caused partly by dead band and partly by lag in the governor response.

Speed Droop and Regulation

Speed droop refers to the relationship between the frequency and operating-

* These diagrams of frequency versus gate are in effect an incremental portion of the speed droop curve. They would consist of straight lines in the case of an ideal governor, but because of compensation and mechanical imperfections they assume the shape of hysteresis loops.

Paper 47-56, recommended by the AIEE committee on power generation for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 12, 1946; made available for printing December 5, 1946.

J. E. Allen is chief of tests at the Pennsylvania Water and Power Company, Baltimore, Md. W. B. Hess is test engineer at the Safe Harbor Water Power Corporation, Safe Harbor, Pa.

piston travel expressed in per cent of normal speed and full piston travel. Regulation substitutes the generator output in place of the operating piston. The distinction between the two terms arises from the fact that kilowatts are not in many cases proportional to piston stroke. Incremental speed droop and incremental speed regulation are the slopes of these curves at any point in question.

Steady State Values

Definitions referring to governor performance have been expressed as steady state values, assuming that the equipment could be subjected to a constant or controlled frequency. In operating tests such a condition never exists and in the following tests it will be seen that as a result of a complexity of transient phenomena the diagrams become modified greatly, primarily by the compensation introduced and other mechanical imperfections. The test results under normal operating condition, therefore, cannot be considered equivalent to steady-state values.

Description of Frequency Recorder

The principal feature of the governor-testing equipment is a new direct-writing frequency recorder, certain features of which have been described briefly in an AIEE discussion,[2] and having the following specifications:

1. Rectangular co-ordinate strip chart 6 inches wide with $4^1/_2$ inches pen travel.
2. High sensitivity, usually 1.0 inch deflection per 0.1 cycle, but adjustable from 0.33 to 1.65 inches per 0.1 cycle. Scale is linear.
3. Maximum pen speed 5.5 inches per second.
4. No hunting and overshoot less than three per cent of full scale deflection at maximum pen speed. When recording frequency, overshoot is negligible.
5. Chart speed is 3 inches per minute.
6. Stylus-type ink pen.
7. Large pen actuating force available, permitting an additional stylus pen to be attached to the pen arm for automatic plotting of frequency versus piston travel on a drum attachment.
8. Sturdy construction to meet the requirements of field testing without sacrificing high sensitivity.

Principle of Operation

The frequency sensitive circuit comprises a small 1,800-rpm 60-cycle-to-60-cycle synchronous motor generator set in which the generator voltage is proportional to the speed or frequency of a synchronous motor driving it. The latter is energized from the source to be measured, such as the system or from the main generator potential transformers in case the unit being tested is isolated from the system. The generator, which is a 60-cycle permanent-magnet type, energizes a nonlinear bridge having its two opposite arms made of a material whose resistance varies inversely with current. Balance at a given voltage or frequency is accomplished by means of an external resistance in series with the bridge. When the frequency changes, the corresponding change in voltage from the a-c generator unbalances the bridge. Balance is restored by changing the resistance in series with the bridge. Thus, the incremental value of resistance required to maintain bridge balance is a measure of the frequency change, and meter calibration becomes a simple function of a linear slide-wire rheostat. See schematic diagram, Figure 1.

The bridge automatically is kept in balance as the frequency varies by means of a high-speed servomechanism or clutch which actuates the slider on the calibrated rheostat *R-16* The clutch functions in a manner similar to a 2-phase reversible motor One winding is energized from the a-c source to be measured and the other winding from an amplifier connected to the bridge output through appropriate harmonic filters. A 180-degrees-phase-angle reversal occurs at the bridge output terminals as the frequency or voltage varies above or below a given initial balance point. This phase reversal provides the directional means for balancing the bridge automatically as the frequency varies. A pen attached to the slider in combination with a strip chart provides the means for recording frequency with respect to time

Magnetic Clutch

The important feature of the recorder is the high-speed reversible magnetic clutch also shown in Figure 1. Essentially it consists of a driving member in the form of a magnetic disk, revolving at 60 rpm, which engages a driven member consisting of a magnetic fork, the prongs of which are hinged and rub with metallic friction against opposite sides of the periph-

Figure 2. Close-up view of magnetic clutch

Figure 3. Linear force exerted by fork at standstill as a function of current through control coils

Figure 4. Linear force exerted by fork at standstill as a function of power input to control coils

ery of the disc. The rubbing friction is controlled primarily by the magnetic attraction between the fork and disc as a result of the alternating current in the reference coil near the disc. Both prongs or legs of the fork are attracted to the disc with equal force, but the disc tends to drive one leg of the fork in a direction opposite to the other leg; consequently, the differential force is zero, and there is no tendency for the fork to move in either direction. If, however, the series-connected control coils become energized because of a bridge unbalance, in proper phase-relation to the reference coil, the magnetic attraction between the two legs of the fork and the disc will be unbalanced. This creates an unbalance in rubbing friction between the two legs and causes the fork to move in a given direction. Reversing the polarity of voltage energizing the control coils will reverse the direction of motion. Linear motion of the fork thus takes place when the frictional forces between the two legs of the fork become unbalanced because of current through the control coils. Effective damping action is provided by the frictional drag or braking effect of one leg opposing the desired motion initiated by the other leg. Hunting and overshooting thus are minimized. Figure 2 shows the magnetic clutch with the driving disc, magnetic fork, reference winding, control coils, and slide wire.

A large force is available for overcoming bearing and pen friction. This force was measured by holding the fork at standstill and passing alternating current through the control coils; a linear relation was found as shown in Figure 3. Because of saturation taking place above 30 milliamperes the maximum measured force was from eight to nine ounces. For a given power input to the control coils below saturation, the large force available for actuating a slide wire, inking pens, and so forth is shown in Figure 4. It is seen that a force of four ounces requires less than 0.1 volt-ampere input. This good performance is realized because the clutch functions as an electromechanical amplifier. Friction between the two legs of the fork may be unbalanced as shown in Figure 3, but this in no way impairs operation because sufficient amplifier gain always is used to maintain negligible pen dead band at bridge balance.

It is well to point out that magnetic clutches in general are capable of very high rates of acceleration, stopping, and reversal. For instance, a recorder employing a magnetic clutch has been described which responds to a frequency as high as 60 cycles per second.[4] Reversing motors have a relatively high inertia and low efficiency as compared to magnetic clutches. The clutch described in this paper requires only one control winding and a simple a-c amplifier to effect directional control in contrast to other types which have two independent electric windings with complicated amplifiers.

General Description

A general view of the recorder is shown in Figure 5. A second stylus pen on an extension records frequency versus operating piston on a large 4.25-inch diameter drum attached to the same end of the cabinet. This cabinet also houses the

Figure 5. Frequency recorder with drum attachment for recording frequency versus operating piston

Figure 6. Synchronous motor generator set in cabinet

amplifier and its power supply. It will be noted that a third stylus pen has been provided to record the piston travel on the same strip chart with frequency. This pen and the drum both are actuated from a common wire attached to the operating piston. Thus, two types of records are obtained simultaneously

1. A strip chart showing the variations in frequency and operating piston with respect to time for determining dead time and rate of response.

2. A card diagram of frequency versus operating piston from which sensitivity, dead band, and speed droop may be obtained readily.

A separate cabinet shown in Figure 6 houses the small synchronous motor generator, nonlinear bridge, and harmonic filter. Various sensitivities are obtained from 0.33- to 1.65-inch deflection per 0.1 cycle by changing taps on the impedance matching transformer *T-7* in Figure 1. The proper phase angle between the control coils and reference coil for maximum force is obtained by adjusting the angular position of the synchronous motor shaft with respect to the a-c generator shaft. The operating piston motion is amplified as much as five to one by means of pulleys on the end of the drum.

Other instruments have been available for obtaining separately either a strip chart record[5] or a diagram of gate motion as a function of frequency with good results,[6] but, so far as is known, the instrument described here is the first one to provide both types of records simultaneously on a single instrument of the direct writing type. Another important feature of the equipment is that the card record is drawn to a larger scale than heretofore possible because of the high sensitivity of the frequency recorder. Furthermore, because of the use of rectangular co-ordinates no distortion is present in the records. It should be recognized, however, that this equipment was designed primarily for testing over-all governor performance under actual regulating conditions and is not intended to replace other methods for making more detailed analysis of phenomena such as relay and pilot valve motion, pressure, power output, rapid transient response, and so forth.[7]

Frequency Deviation Meter

No attempt has been made to calibrate the meter in terms of absolute frequency, because the application intended did not justify this refinement. It is primarily a frequency deviation meter and provision has been made by means of a variable resistance *R-17* in series with the

bridge to shift the pen to any desired position on the chart.

Temperature Compensation

Because of the negative temperature coefficient of resistance of the two nonlinear arms in the bridge, it has been necessary to compensate the recorder for changes in ambient temperature. This has been accomplished by the use of nickel compensating resistors *R-5* and *R-6* connected in series with the bridge. Drifting because of temperature, except for a warming up period of about 20 minutes, has been reduced to a negligible value for ordinary room temperature variations. It has not been necessary to compensate the a-c generator for ordinary room temperature variations.

Analysis of Records

Strip Charts

The strip-chart records of frequency and piston motion need not be discussed to any extent because their analysis requires no special technique. It should be emphasized that they provide a valuable adjunct to the drum records by permitting an analysis to be made of dead time and rate of response.

Incremental Speed Droop

The card obtained from the drum consists of a multiplicity of diagrams superimposed on a common axis. By means of pulleys on the drum the piston travel is amplified so that the diagrams are greatly elongated and resemble an ellipse, with the major axis representing the slope of the speed droop curve. The diagrams are the result of the governor's responding to the frequency changes taking place on the system under normal operating conditions. A sufficient number of them is required to establish the slope of a common major axis, and ordinarily only five to ten minutes are required, depending on the system frequency changes. After the card is detached, a line or common major axis is drawn through the diagrams by visual inspection and its slope, expressed in per cent incremental speed droop, is determined by applying the proper multiplying factor between piston and drum motion. No replotting and no further working up of data are necessary. Typical cards with sample calculations are shown in Figures 13–14.

Sensitivity and Dead Band

The frequency change corresponding to the vertical width of the diagrams measured at the minor axis is considered a measure of sensitivity. Good or bad governor performance usually is interpreted as being a function of the total width and shape of the superimposed diagrams. Once an acceptable standard has been established the card diagrams and strip chart records become an important adjunct to the routine maintenance of governors.

Dead band may be obtained by noting the vertical portion of those loops in which there is no change in gates or valves for a given frequency change

Direct Recording of Incremental Speed Regulation

The speed droop obtained in the above manner obviously will be based on the travel of the operating piston or gate. If desired, incremental speed regulation may be obtained by referring to a test curve of gate travel versus kilowatts output at the point of test. However, this practice is somewhat inaccurate and laborious, and therefore further developments in instruments were made for the direct measurement of frequency versus kilowatts on a single card so that incremental speed regulation may be obtained readily without additional plotting. This is accomplished by actuating the drum by

Figure 10. A card diagram of frequency versus gate-operating piston and strip-chart record of Safe Harbor number 7 unit regulating on the system. Before maintenance

Dashpot by-pass 70 degrees (normal)
Incremental speed droop = 3.2 per cent

Dashpot by-pass 70 degrees (normal)
Incremental speed droop = 4.2 per cent

means of a special recording wattmeter having high sensitivity, large torque, and negligible time lag. Such a recorder in combination with the drum and frequency meter is shown in Figure 7.

The recording wattmeter is restricted in its application to small direct currents or potentials such as are available from telemetering circuits. Advantage was taken of a General Electric Company torque balance telemeter installed on each generator at Safe Harbor. These telemeters are a source of direct current proportional to the kilowatt output. The special recorder employs a null balance system whereby the voltage drop across a fixed resistance in the telemeter output circuit is used to buck a reference voltage in a self-balancing potentiometer circuit. A slide wire rheostat calibrated in kilowatts keeps the potentiometer in balance as the telemeter output varies. A 2-phase reversible motor energized from an a-c amplifier automatically actuates the slider on the balancing rheostat. A converter of the vibrating reed type changes the unbalanced direct voltage to alternating current. The motor, amplifier, and converter are standard components made by the Brown Instrument Company for their "Electronik" recording instruments. The slider on the above rheostat has a pen attached for recording on the same strip chart with frequency, as shown in Figure 7. A rack and pinion couples the motor shaft to the slider and pen, and also to the drum through a system of counterweighted pulleys for mechanical amplification as shown in Figure 7. Maximum pen speed is 1.4 inches per second. It will be noted that a third pen has been added to record operating piston motion on the strip chart simultaneously with kilowatts and frequency.

The cards obtained have rectangular co-ordinates and are quite large because of the high sensitivity of recording both frequency and kilowatts. The combined instrument thus gives two types of records simultaneously

1. A strip-chart record of frequency, piston motion, and kilowatts with respect to time.

2. A card diagram of frequency versus kilowatts from which incremental speed regulation may be obtained readily without any further plotting.

The card is worked up in the same manner as a frequency versus operating-piston card by visually drawing a line or common major axis through the superimposed figures and calculating its slope after applying the proper instrument calibrations for frequency and kilowatts.

In addition to testing the individual units in the above manner, the generator output telemeters were totalized so that the incremental speed regulation of the entire plant was recorded on a single card.

Testing Applications

The equipment has been used extensively in checking governor performance at the plants of the Safe Harbor Water

Figure 12. A card diagram of frequency versus gate-operating piston and strip-chart record of Safe Harbor number 7 unit regulating on the system. After maintenance

Incremental speed droop = 4.7 per cent

Power Corporation and Pennsylvania Water and Power Company. The Safe Harbor station contains seven 42,500-horsepower Kaplan and two 3,100-horsepower Francis units. All machines have Woodward governors with motor-driven fly balls. At Holtwood there are ten units of the Francis-type rated from 13,500 to 20,000 horsepower. The governors are all I. P. Morris double-floating lever-type with mechanically-driven flyballs. There are two 12,500-kilowatt turbogenerators in the steam station with General Electric Company governors.

These plants are a part of the interconnected systems comprising most of Federal Power Commission areas *5* and *6*. Geographically these areas include Eastern Pennsylvania, New Jersey, Maryland, Delaware, and the District of Columbia. The usual generating capacity of the group is in excess of 4,000,000 kw. There is no automatic frequency control; average frequency for electric time is regulated manually by a designated station with all other frequency regulation taken by the individual unit governors.

During the low river flow periods the hydro units at Safe Harbor and Holtwood have the governors free to assist the other stations on the interconnected system in regulating frequency. On an average year this amounts to about 75 per cent of the time at Safe Harbor and less than 50 per cent of the time at Holtwood. For effective regulation and economy of operation it is important to have correct governor action free of hunting, creeping, and other irregularities. To this end the testing equipment has been a valuable aid in locating malperformance and in measuring the effect of adjustments and corrective measures. It is not within the scope of this paper to discuss the effects of governor performance on system operation as the subject has been covered competently by others.[8]

Speed Droop and Regulation of Hydraulic Turbines

Because the greater portion of this work has been in connection with governors on hydraulic units an explanation of some of the characteristics of these machines may be helpful to those who are not familiar with this type. It has been the practice of the manufacturers to base the speed droop characteristics of the governor on percentage of gate stroke rather than power output. This relationship on the more recent governors is substantially a straight line over the full range of

Figure 14. A card diagram of frequency versus gate-operating piston and strip-chart record of Safe Harbor number 4 unit regulating on the system

Positive centering dashpot, drum ratio = 4.8, total stroke = 29.625 inches, rated speed = 60 cycles

Incremental speed droop = 3.2 per cent

Figure 15. A card diagram of frequency versus gate-operating piston and strip-chart record of number 4 unit at no-load speed, not paralleled

Figure 16. A card diagram of frequency versus gate-operating piston and strip-chart record of number 4 unit at no-load speed, not paralleled

gate stroke and therefore is proportional for equal increments of gate stroke. However, there may be considerable variation in incremental speed regulation over certain ranges of gate travel because the power output of a hydraulic turbine is not a linear function of gate opening over the full range. Figure 8 illustrates typical curves of gate-power relation for three different types of turbines. By combining the information of Figure 8 with the speed droop characteristic of the governor a speed–power curve can be obtained; the slope of this curve at increments of power output establishes the incremental speed regulation curve. The steady-state incremental speed regulation for the Kaplan and propeller types with an assumed linear speed droop of five per cent is shown in Figure 9. Because the characteristics of the Francis turbine are similar to the propeller type the incremental regulation curve will be practically the same.

The speed droop characteristics of a governor may be modified to compensate for the nonlinear power-gate curve. Within the normal operating range of the Kaplan units the compensation would be gradual and of a low order. However, with respect to the propeller or Francis types it will be noted that a steep rise occurs at the point of maximum efficiency where the unit is most likely to regulate. From the standpoint of stability, caution should be exercised in attempting to fully compensate for the steep rise.

Routine Maintenance Checks

Routine checks of governor performance have been used as a guide for determining when governor maintenance or adjustment is needed. Figure 10 shows the performance of a governor before a periodic maintenance and inspection period. The strip chart indicates very poor governor action in that the gate-operating piston has a tendency to follow only the general trend of the average frequency and offers little helpful operation in regulating the swings. The card diagram of frequency versus operating piston, taken simultaneously with the strip chart, shows a very insensitive governor with the average width of diagrams approximately 0.10 cycle per second or 0.17 per cent of rated speed. The straight vertical lines extending across the diagram are, according to definition, dead band. This type of diagram is indicative of friction in the primary elements of the governor.

Maintenance inspection revealed friction in the main-relay valve-packing gland, the ball-head bearings, compensating dashpot plungers, and also an 0.08-inch off center setting of the small dashpot plunger. The charts of Figure 11 show the operation of this same governor after the above conditions were corrected. The strip chart shows a decided improvement in governor performance with the gate piston following all of the major frequency swings with little time delay. The card diagram indicates an average sensitivity of 0.05 cycle per second or 0.08 per cent of rated speed. The actual dead band is 0.025 cycle per second or 0.04 per cent of rated speed.

Effect of Compensation

The variation in the width of the minor axes of the different superimposed loops is quite evident in Figure 11 A portion of it was the result of overcompensation on the higher rates of frequency change To illustrate, Figure 12 shows a test with the compensation reduced by opening the dashpot by-pass; the figures are more uniform and not nearly so wide. The strip chart also shows a more active governor with the gate following even the small fringe variations in frequency

Compensating Dashpot Investigation

One of the problems encountered at Safe Harbor was that of sluggish response to the load adjusting control. After the initial movement the turbine gates had a tendency to creep making it difficult to adjust the unit loading promptly and accurately. Test results showed that this

Figure 17. A card diagram of gate-operating piston versus blade angle of Safe Harbor number 1 unit taken at slow traversing speed

Kilowatts per per cent stroke = 445

Figure 19. A card diagram of frequency versus total load and strip-chart record of Safe Harbor station regulating on the system

Head = 55 feet
Load range = 170–185 megaw atts
Incremental regulation = 2.70 per cent

same response prevailed when the machine was regulating frequency See Figure 13. Note the poor governor response and gradual drift in the gate motion. The card diagram illustrates very erratic governor action; the small complete loops occurring either side of the central axis indicate false movements coming from the compensating mechanism. The steep droop characteristics of the larger loops, designated by the dashed line, are also indicative of trouble coming from the same source.

Further investigation showed the spring on the compensating dashpot plunger was failing to bring the mechanism to a definite center position, thereby establishing with each speed change a different neutral position for several of the governor components. This particular dashpot design employed a spring which in neutral position should have been in zero tension, and, therefore, the slightest friction caused it to position itself to one or the other side of actual center. Furthermore, the low order of centering force exerted by this particular spring application produced spasmodic motion and produced the erratic diagrams pointed out previously.

The dashpot was replaced with a positive centering type in which the spring always is exerting a force to hold the plunger in central position against a positive stop, thereby minimizing the effect of friction. The results of operation after this change are shown in Figure 14.

Tests made at no-load speed with the generator off the bus after the dashpot change indicated better speed control and a very drastic change in droop characteristics. See Figures 15 and 16. The incremental speed droop of the original dashpot was increased greatly because of the effect of friction. To provide a cushion effect minimizing swings on sudden load rejection, the speed droop has been increased purposely to approximately 10 per cent in the 0 to 15 per cent gate opening range. Note that the diagram with the positive centering type of dashpot shows a much lower speed droop than the original dashpot, and the actual measurement now checks the

Figure 20. A card diagram of frequency versus gate-operating piston of Holtwood number 5 unit regulating on the system

Gate opening 73 per cent, drum ratio = 4.8, total stroke = 23.5 inches
Incremental speed droop = 4.6 per cent

nominal value. It has been found that friction regardless of its origin tends to increase the incremental speed droop.

Lost Motion Recording

Many times the advantages of a good governor are lost because of play in the mechanism between the operating piston and the gates, blades, or valves controlling the speed or load. The percentage effect may be appreciable on small movements such as are required on system frequency regulation. A very accurate evaluation of the amount of lost motion between the operating piston and blades on a Kaplan unit has been obtained by means of X-Y recording, whereby motion from the operating piston rotates the drum as one axis, and motion from the blades actuates a pen as the other axis. The width of the elliptical diagram is a measure of the magnitude of lost motion. Such a diagram taken at slow traversing speed is shown in Figure 17. Subsequent studies have shown the lost motion to be in the Kaplan control valve and in the Kaplan mechanism itself

Power Response

In our work we have carried the study with X-Y recording from the motion of the operating piston to the power output of the generator. Thus in Figure 18 the generator output is recorded as a function of operating piston motion under regulating conditions. Instead of the expected nearly straight line characteristic with a slope of 1,200 kw per per cent stroke, as indicated by calculations, the diagram is wide, irregular, and with an average slope of only 445 kw per per cent stroke.

The strip-chart record of frequency, gate, and power output, Figure 18, shows the relative time lag between the operating piston and power output. It will be noted that the piston responds to the frequency within 0.5 second as shown at B, but the power at C still is dropping from the previous frequency change at A and does not respond in the proper direction until at D, 9.5 seconds after the frequency change. This example was exceptional; on the average the lag appears to be five six seconds.

A small portion of the lag can be ascribed to inertia of the control system and transient hydraulic effects; the greater part, however, is the result of lost motion between the gates and blades. Consequently, the sensitivity is decreased and the per cent incremental speed regulation increased as much as three times the calculated value.

Figure 21. A card diagram of frequency versus gate-operating piston of Holtwood number 5 unit regulating on the system

Gate opening 29 per cent, drum ratio = 4.8, total stroke = 23.5 inches
Incremental speed droop = 6.2 per cent

To reduce the degree of overspeed on our Kaplan units the closing time of the blades has been increased to 15 seconds as compared to 6 seconds for gate closure. No time lag has been introduced purposely which would retard the initial blade movement. Under normal frequency regulation, the above slow traversing times have been found by actual test to have little or no effect on the blade or gate response because the rate of frequency change does not require either of them to travel near the maximum rates.

Miscellaneous Tests

Incremental Speed Regulation of Safe Harbor Station

Where telemeter totalizing equipment is available regulation diagrams can be made of an entire station or group of stations. Figure 19 is a diagram of the Safe Harbor station with all units paralleled and governors regulating. The power lag described in the previous discussion can be seen on the strip chart; it is reflected also in the width of the diagram and higher than calculated per cent regulation. However, the actual slope or incremental speed regulation is still only 2.7 per cent, and the governors are seen to be very responsive to frequency changes

Holtwood Hydro Units

Figure 20 shows incremental speed droop diagrams from a 12,000-kw Holtwood hydro unit operating at 73 per cent gate. Figure 21 shows a diagram from the same unit operating at 29 per cent gate; note the difference in sensitivity at these two gates. The unit seldom is operated at this low gate, and the increased friction in the working parts of

Generator load = 95 per cent rating, drum ratio = 31.75, total stroke = 6.5 inches
Incremental speed droop = 4.5 per cent

Figure 22. A card diagram of frequency versus valve-operating piston of Holtwood Steam Station number 15 unit regulating on the system

Incremental speed droop = 5.3 per cent

Figure 23. A card diagram of frequency versus valve-operating piston of Holtwood Steam Station number 16 unit regulating on the system

the governor because of inactivity is quite evident.

Holtwood Steam Plant

By including additional step pulleys in the setup, thereby further amplifying the drum motion, diagrams can be made on steam units with relatively small total stroke. Diagrams, Figures 22 and 23, were made on the Holtwood steam turbines where the total travel of the valve operating piston is 6.5 inches.

Compensating Dashpot Oil

Seasonal temperature changes and the resulting effect on the viscosity of the compensating dashpot oil have a decided effect on the performance characteristics of the hydro governors. This condition can be remedied by changing the adjustments on the dashpot or using heaters in cold weather; however, our experience has shown that standardization of settings is desirable. At the present time tests are being made on the more constant viscosity silicone oils.

Conclusions

1. Improved instruments for testing governors have been described and numerous examples shown of applications to hydro and steam units. These examples demonstrate that the many factors affecting governor performance are shown readily and can be evaluated by the card diagrams and strip chart records. The effects of maintenance, adjustments, and corrective measures therefore are determined quickly and easily.

2. The method of testing with card diagrams of frequency versus gate offers a convenient means of establishing practical governor performance standards and maintaining them throughout the life of the equipment.

3. Adoption by the industry of methods of testing similar to those described in this paper would provide a common basis for analyzing governor performance. More general use of this method of testing would be promoted by the early adoption of suitable terms defining the characteristics of the frequency versus gate diagrams obtained under operating conditions.

Discussion

G. J. Vencill (Union Electric Company of Missouri, St. Louis, Mo.): It is apparent that the authors have considerable interest in the subject of governor analysis and testing from the time and effort that must have been required to develop the equipment used. They are to be complimented on the soundness and completeness of their presentation. The use of such instruments in testing governors to determine the need for and effectiveness of maintenance work should eliminate practically all the uncertainty usually present in such determinations. Without definite information on governor performance, it is so easy to assume that as long as it is quiet it is good.

Our company has fitted a General Electric photoelectric frequency meter with an auxiliary table to make the diagrams of frequency versus operating piston position, and has found it useful in tracing locations of trouble. The simultaneous recording of the strip chart and diagrams, while convenient, is not regarded as necessary, since the same actions recur indefinitely and can be recorded separately. We have not made direct comparisons of kilowatt output with frequency, but think it would be very desirable to do so since that is really the ultimate result of the regulating action.

The frequency–gate diagrams provide a very simple means of analysis where the governor has no compensation as is usually the case with a steam turbine. Where compensation is used, the shape of the diagram will depend considerably on the speed with which frequency changes, and the characteristics of the frequency pattern. This would need to be taken into consideration when drawing conclusions from the records. In any case the strip chart record is necessary to determine time lag.

Figure 1 of this discussion is two sample diagrams showing performance of two steam unit governors on our system, both of which are quite sensitive.

Figure 1. Sample performance diagrams

R. Sheppard (nonmember; General Electric Company, Schenectady, N. Y.): The contribution of the speed governor controlling the steam or hydro unit once its generator is phased in with a large interconnected system of relatively constant average frequency is largely determined by the governor's ability to accurately respond and correctly direct the positioning of the inlet valves in response to the minute and relatively slow frequency variations constantly occurring. The dead band of the governor mechanism, as defined by reference 1, is the total magnitude of the sustained speed change within which there is no resulting measurable change in the position of the governor controlled valves. This dead band or insensitivity of the governing mechanism is the one characteristic which has so much to do with the width of the frequency fringe drawn by instantaneous frequency recorders on so-called constant frequency systems. Automatic frequency control or careful manual control can do little to narrow the characteristic system fringe band however well they may maintain the average frequency. It is believed that a reduction of such frequency fringe bands on existing systems is possible and may slowly come about as additional new prime movers with governors of small dead band are added to systems.

At least two central station systems have undertaken a limited program of replacing a few older governors having poor dead band characteristics with modern accurate low dead band governors. The improvement and effect upon the frequency band will be carefully studied when these replacements are installed. It is hoped that tie-line and frequency regulation will be simplified and made easier by the conversion of an appreciable portion of the steam prime mover capacity to such low dead band characteristic governors.

Figure 2. Steam turbine servopiston travel versus system frequency showing poor dead band of older type governor

Figure 3. Steam turbine servopiston travel versus system frequency showing reasonable dead band of an oil relay governor

Figure 4. Steam turbine servopiston travel versus system frequency showing good dead band of improved oil relay governor

The development of instruments described by the authors, and their use to study the insensitivity of governor mechanisms has assisted governor manufacturers in the improvement of their product. Such studies for the most part have first been conducted in hydro and steam stations. The writer and his associates have used a photoelectric straight dead band diagram recorder similar to the early type first developed by Allen. Governor mechanisms of some 60 large steam turbines and seven hydro units have been studied on their respective power systems. These studies clearly revealed which types of speed governors had consistently poor sensitivity and those which were superior. The knowledge gained from such studies has materially aided in the adoption of improved governors and the rejection of those with poor sensitivity.

Figures 2–5 are examples of governor dead band hysteresis cards of progressively smaller dead band governors. All have been taken on steam units whose governors unlike those of hydro units had no time delay speed compensating dashpot mechanism, and in general, each had a nominal 5 per cent over-all steady-state speed regulation. Any small time lags in the positioning of the servo motor piston were largely due to the normal time for oil to flow through the relays to restore the servo pilot back to port equilibrium. In steam turbine governors of the non-compensated type these time lags are small.

Figure 2 illustrates the dead band of a governor which, although it exhibited no instability and suffered no noticeable difficulties, contributed little to the accurate regulation of the system and certainly aggravated the characteristic frequency fringe of the system to which it was attached. Unfortunately the nature of the inherent friction and drift in the governor of this example was of such a nature that little if anything could be done to improve it as far as maintenance attention or parts replacement are concerned.

Figure 5 is an unusual governor mechanism and approaches the ideal in accuracy and dead band. Notice the momentary deviations from the true speed-travel line caused by rather fast frequency changes of very small magnitude.

The new instrument described by the authors which simultaneously records the frequency and load as a function of time on a strip chart plus the $X-Y$ gate-frequency hysteresis loops should be very helpful in interpreting the dead band loops since it is believed the rate at which the frequency is changing has some bearing on the dead band width. It is suggested that the authors take a series of gate position dead band cards of only long enough time duration to permit the pen to form one or two loops. These cards could then be studied knowing the rates at which frequency was changing. Thus, for a given governor there could be established the relation between effective dead band and rate of change in frequency.

The authors are to be congratulated for their valuable work in the development of speed governing of large central station prime movers.

C.L. Avery (Woodward Governor Company, Rockford, Ill.): The authors of this paper are to be complimented on a very clear and complete description of the instrument which they have developed for testing governor operation. The instrument described is of particular interest because of its ability to draw both card diagrams and strip charts simultaneously. Both types of diagrams are required for a complete analysis of governor

Figure 5. Steam turbine servopiston travel versus system frequency showing unusually small dead band of an improved oil relay governor

operation, hence the ability to make both types of records at the same time considerably reduces the testing time.

While the authors state that "no attempt has been made to calibrate the meter in terms of absolute frequency," and it is evident that meter drift during the time to make a run is negligible, it would be of interest to know what the drift over an extended period of time would be. It is distinctly of advantage to be able to shift the position of the pen on the chart, and it should be noted that such a shifting of the pen does not affect the sensitivity of the instrument.

A program of periodic testing of governing equipment is to be strongly recommended as a means of determining when the operation is becoming so erratic that maintenance work should be done. By such a program, incipient difficulties can be detected and the necessary maintenance performed before system operation is adversely affected.

The diagrams showing the contrast between the operation of unit 4 with the original dashpot (Figures 13 and 15 of the paper) and with a positive centering dashpot (Figures 14 and 16 of the paper) are very interesting. The positive centering dashpot was first used at Safe Harbor, Pa., and is of especial advantage on a very active load such as is supplied by the Safe Harbor Plant. The difference in construction of these two types of dashpots is illustrated by Figures 6 and 7 of the discussion. The transmitting plunger e of the regular type (Figure 6) is returned to its null position by the push-pull spring a whereas the plunger of the positive centering type is returned to null position by the two springs b and c either of which can be separately adjusted for preload at the centering position. Incidentally, the values of "dashpot by-pass" indicated on the figures of this paper refer to the relative opening of the needle valve d.

The charts indicate that the positive centering dashpot allowed a larger opening of the by-pass and also that the ratio of movement of the receiving plunger f to gate travel may have been substantially reduced.

B. R. Nichols (nonmember; Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The authors are to be congratulated on their contribution to the study of gov-

Figure 6. Dashpot construction

Figure 7. Dashpot construction

ernor performance, and the development of the simplified highly sensitized recording instrument for recording the performance of governors operating under field conditions.

This type of work should be encouraged, particularly among the operating department of power companies not only to learn more about the requirements of new governors, but also to improve the performance of existing governors.

The writer has observed that there are many governors, particularly of the older installations, throughout the country that are not performing correctly. Some of these governors have never been adjusted correctly because of various reasons, others have been adjusted to improve a particular condition without regard for other operating conditions. A common adjustment of this type among some operators is to tighten the dash pot by-pass valve if the turbine gates swing too much when the unit is off the line, instead of investigating the cause of the swings.

In order to obtain the best performance from the governors on a system, it is necessary to make numerous observations of the load and frequency characteristics of the system. These studies often require considerable time and for these reasons the studies can best be made by power company engineers, equipped with the proper instruments, and, as pointed out by the authors, it would be relatively easy to make routine maintenance checks on the governors after a governor performance record has been made with the most satisfactory governor adjustments. The instrument developed by the authors, combining high sensitivity with both strip chart and card diagram records should be very satisfactory for this type of inspection.

With reference to the authors' comments on the compensating dashpot, our experience has shown the necessity of a definite centering device if the governor is to accurately respond to system speed changes. This centering spring should exert a force at center position which is considerably greater than the viscosity drag of the oil film between the cylinder and piston and other functional forces in the mechanisms which are operated by the dashpot.

The rigidity of the restoring mechanism between the governor and turbine shifting ring is also of importance for accurate positioning of the governor mechanism during operation.

We have whenever possible used the rod and lever type of restoring mechanism because this type of mechanism, if properly designed, will transmit the shifting ring motion to the governor very accurately.

The cable type relay must have a heavy weight or spring attached to one end to maintain a tension in the cable.

This mass has to be accelerated when the shifting ring moves in a direction to lift the weight and when moving in the reverse direction of the movement of the weight must be quickly stopped at the end of the shifting ring movement. The inertia of this mass changes the tension of the cable.

The change of tension on the cable is more pronounced on the governors that respond quickly to system speed changes.

The spring method of maintaining cable tension reduces the inertia effect on the cable tension, but the spring must be made with many coils to keep the difference in cable tension at a minimum between the ends of the relay strokes. This condition requires a long spring which is difficult to locate in the governor assembly.

Paragraph 3 of the authors conclusion is a very worthy suggestion. The industry can, however, avoid many of the disappointments of the past by setting forth an acceptance test code which will state the governor performance that is expected when the governor is installed. This code should also provide suitable time and conditions for these tests. Quite frequently a customer will spend millions of dollars and years of time to develop and build a power project, but when one of the last phases of completion arrives, that of adjusting the governor, he is so eager to start generating kilowatts that he cannot spare another day to properly test and adjust the governor. This is one of the reasons why he sometimes discovers at a later date, and to his disappointment, that his governor is not performing as he had expected it to perform.

F. Oppenheimer (Pennsylvania Water and Power Company, Baltimore, Md.): The testing method described applies only when the unit is on system but can be applied over full frequency range (that is, equal to speed droop, say 5 per cent) if a means is available to load the unit at frequencies of 95 per cent of normal. This is not usually possible, but several other schemes can be used which give similar data over the full range. Scheme 1 consists of driving the ballhead of the unit being tested from a separate source of adjustable frequency while the main generator itself is on the system carrying load. The frequency could be varied over a range sufficient to change the main generator output from full load to no load. Scheme 2 consists of again driving the ballhead at variable frequency but with the main unit shut down This is not true operating condition but will give piston stroke versus frequency. Scheme 3 consists of taking two generating units off the line, shutting steam or water off one of them and driving it by means of the other unit. Full range of speed variation is possible (by throttle or hand control of the driving unit if necessary) but again this is not under true operating condition. Just which of the three schemes, if any, is used

Figure 8A. Incremental speed droop of the Safe Harbor unit 5

Dashpot by-pass = 70 degrees (normal)
Incremental speed droop = 3.5 per cent

Figure 8B. Performance diagrams of governor operation after periodic overhaul

eventually must be determined by the desires of the individual.

It is logical to inquire of what practical use are instruments and test methods described in the paper. An example of the practical results of routine testing is indicated by Figure 8 of the discussion which shows the performance of the governor of a waterwheel after a periodic overhaul. We try to test governors before and after such outages in the hope of detecting imperfections which may need special attention during the outage and then to make sure the governor is at least no worse than before. A glance at this chart gives an immediate impression of good operation without even measuring it. The experienced eye would see high sensitivity, narrow speed droop curve, and small time lag.

J. E. Allen and W. B. Hess: Precise temperature compensation was not attempted and therefore some drift, as referred to by Avery, would be expected if the temperature change was sufficiently large. Tests have shown that, after the initial warming up period of about 20 minutes, the drift during the period of governor test was negligible. No tests have been made for an extended period.

The suggestion submitted by Sheppard concerning single loop diagrams has been used successfully in making studies of units running at speed no-load off the bus. This diagram has led to improvements in speed control for synchronizing. The spiral type of diagrams obtained by manually disturbing a governor are also valuable for investigation of unstable conditions.

Six of the Kaplan units at Safe Harbor, Pa., have the rod and lever type connections between the gate links and the blade control valve; one unit has weighted cable connections. So far as lost motion is concerned, our tests indicate very little difference between the two types. The greatest amount of the time lag has been found in the blade control valve lap and lost motion between the gate operating piston and the gate link to which the blade mechanism is attached. Considerable improvement could be obtained by connecting the blade control linkage directly to the gate operating piston rod. There is some question, however, regarding the increased duty this method would impose upon the blade operating mechanism if the governors are maintained at their present sensitivity. Nevertheless, it is quite evident that the gates and blades must operate in the proper relationship to obtain the maximum effective regulation of the Kaplan type turbine.

The card diagram included in Oppenheimer's discussion is the best thus far obtained on a hydraulic turbine governor. Past experience and continued routine checks will assist greatly the improvement of other governors and aid in maintaining the performance indicated by these diagrams.

Appreciation is expressed to the authors of the excellent discussions which have been submitted. The subjects covered and additional descriptive material submitted greatly increase the scope of the paper.

Automatic Control of Hydroelectric Generating Stations

M. J. BROWN
MEMBER AIEE

W. A. DERR
ASSOCIATE AIEE

Synopsis: This paper discusses hydroelectric station equipment, operating procedures and the factors involved in applying automatic control. Hydraulic governors and the types of water wheels (impulse, reaction, fixed propeller, and adjustable propeller) are described from the electrical engineer's viewpoint. A typical automatic control diagram is shown for each of the two methods commonly employed for accelerating the generator and synchronizing it with the system. In one method, termed self-synchronizing, the machine circuit breaker is closed at less than synchronous speed, and the machine synchronizes after its field is applied. In the other method, automatic speed matching and synchronizing equipment bring the machine on the line at correct voltage and phase angle. Considerations involved in applying supervisory control to automatic hydroelectric stations are presented.

HYDROELECTRIC STATIONS are particularly well adapted to automatic control. As they are justified economically only if their operating expenses are in keeping with the value of their generating capacity, many small installations must be completely automatic to compete commercially with other sources of power. An important consideration is the random availability of their generating capacity. Except in large installations, hydroelectric power must be considered as an auxiliary to steam power. It can be used either for short periods when extra generating capacity is needed, or for long periods when an abundance of hydraulic power is available. Automatic control of hydroelectric stations is favored by the relative simplicity of control of both the prime mover and the stored hydraulic energy which drives it.

Paper 47-57, recommended by the AIEE committee on power generation for presentation at the AIEE winter meeting, New York, N. Y., January 27–31, 1947. Manuscript submitted November 8, 1946; made available for printing December 26, 1946.

M. J. Brown and W. A. Derr both are with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Station Elements

The elements controlled in an automatic hydroelectric station are the headwater valves or gates, the hydraulic turbine gates or jets, the turbine governor, the lubrication system, the water wheel generator, and the switchgear. The latter includes control relays, protective relays, the voltage regulator, the generator field circuit breaker, and the generator line circuit breaker.

Each of the foregoing elements has a particular function in the over-all operation. The headwater valves, or gates, render the hydraulic equipment inoperative and conserve water during shutdown periods. The turbine gates under the control of the governor admit water in proportion to the load requirements of the turbine. The lubrication system establishes a lubricating film on the bearings during starting, maintains it during operation, and circulates the lubricant so that it can be cooled. The switchgear provides control and protection. The voltage regulator controls the excitation of the machine in keeping with the voltage requirements and demand for reactive power output of the generator. The generator field circuit breaker provides a means of field interruptions during faults, and thereby minimizes damage to the generator and other equipment. The generator line circuit breaker serves to connect the generator to the system after the generator has been started. It also disconnects the generator from the system prior to shutdown or following an electrical fault.

Headwater Control

The headwater gates, or valves, may be of various designs. They have been built in the form of needle or conical plug valves, butterfly valves, gate valves, and sluice gates. These gates are operated either electrically or hydraulically. No details of the cont ol of these gates are included in the following description, because the control is straightforward and can be added to the other operating functions without difficulty. There also may be requirements for the control of diversion and reject spill gates. These requirements are similar to those for headwater gates.

Hydraulic Turbines

The arrangement and location of a hydroelectric power plant will depend upon the developed head, river flow conditions, means of introducing water to the plant, means of conducting water from the plant, and the total installed capacity. Although these factors do not affect automatic control directly, they do determine the equipment that will be used, and this in turn will have its bearing on the demands placed upon the automatic control.

It is the turbine design and the associated governor equipment that will be of most interest to the electrical engineer. Turbines will be of one of four types, three of which are shown in Figure 1. Installations using a high speed input (above approximately 800 feet) generally will employ impulse or Pelton turbines, one type of which is shown in Figure 1*A*. In the moderate head installations (range of approximately 60 to 800 feet), the reaction or Francis type turbine, Figure 1*B*, usually will be encountered, and on low head installations (below approximately 70 feet) the fixed and adjustable blade propeller or Kaplan type turbines, Figure 1*C*, will be found most frequently. Often, the hydraulic engineer has a choice between the use of a reaction type turbine or propeller type turbine. The propeller type turbine will operate at a higher speed (approximately 50 per cent).

A (left). Impulse type
B (below). Reaction type
C (right). Adjustable propeller type

Figure 1. Three types of water wheels

The Water Wheel Governor

The water wheel governor has a multiplicity of tasks assigned to it. It is the central control point for the prime mover operation and is the device through which the automatic starting and stopping equipment functions in its relations with the prime mover. The duties performed by the governor are as follows:

1. Initiation of water flow to the turbine at start and its discontinuation when stopping. This in practice will be the opening or closing of the wicket gates, guide vanes, or jets, of the reaction, propeller, or impulse turbine, as the case may be. This particular function is executed under the direction of the automatic equipment on the switchboard.

2. Control of turbine speed

A. During starting. The governor, in one method of starting controls the turbine speed under the direction of a speed matcher on the governor or on the switchboard. In an alternative method of starting, the governor brings the machine to full speed without any attempt to match existing line frequency.

B. After the generator is on the line. In those cases where the hydroelectric generator parallels with a large system, its turbine speed will be determined by system frequency. However, in the case of an isolated generator or one which represents a large portion of system capacity, the system frequency and turbine speed can be determined by the governor of that machine alone.

3. Control of the turbine loading. The governor must provide means by which the turbine will take on or drop off load as the load on the generator or system changes. It also must provide an adjustment which will determine how the turbine will share load changes with other power sources.

4. In some special cases it provides means for operating the generator as a synchronous condenser at normal frequency with no flow of water to the turbine and at the same time provides for opening the gates in the event that frequency drops

As practically all automatic hydroelectric stations will be connected to large systems, it will be of interest to examine the operating requirements of a hydroelectric station when operating as part of such systems. Consider Figure 2. This is a diagram showing the characteristics of two generators, having respectively one per cent and two per cent speed droop, connected to a large system. The large system approaches an isochronous characteristic in that it operates with little change in frequency as load changes. As long as system frequency remains constant, the load supplied by generators *1* and *2* will be constant and of the value indicated by point *a*. If the system frequency drops, generator *1* with one per cent speed droop will show a considerable change in load as indicated by the intersection of the dotted line with the characteristic line of generator *1*. The load on this machine will increase from the value indicated by point *a* to that of point *c*. However, generator *2* with a two per cent speed droop will show less change in load with change in system frequency. The speed droop characteristic of the governors, therefore, should be adjustable so that load changes will be taken on generators which can accommodate them best. Governor sensitivity, which is a nonadjustable factor, figures in the distribution of load changes. The more sensitive governor will respond to frequency changes faster and by being more prompt will cause its prime mover to take a greater share of the load changes than the prime mover controlled by a less sensitive governor.

The Lubrication System

The lubrication system includes the facilities required for lubricating both the turbine and generator.

In most cases the generator lubrication system is self-contained and, therefore, does not require auxiliary pumps. However, horizontal generators may have high pressure bearing lift pumps for use during starting. Likewise, some high speed generators will use pumps for circulating the lubricant after the machine is running.

Automatic control must consider the operating requirements of the lubrication system during start, running, and shutdown.

Water Wheel Generators

Water wheel generators fall into one of two general classes, depending upon whether they have horizontal shafts or vertical shafts. In general, the impulse turbine installations require horizontal shaft machines and develop speeds between 300 and 1,000 rpm. The other turbine types require vertical shaft machines, which they drive at speeds ranging generally from 100 to 300 rpm. Either type is subject to severe overspeeds, and rotors are constructed to withstand the resulting stresses.

The slow speed of rotation demands high excitation current for the generator field. This reflects on the ratings of the field circuit breaker equipment and has a bearing on the voltage regulator application.

The automatic sequence in some cases places demands on the amortisseur winding for synchronizing torque. When

Figure 2. Load-speed curves of generators of different speed droop characteristics connected to a large system

control of this type is contemplated, the capacity of the amortisseur winding must be investigated to determine its adequacy.

A water wheel station is shown in Figure 3. The switchgear is located adjacent to the left wall. The governor cabinets are located in front of the switchgear opposite each generator. A cross section of a station of this type is shown in Figure 4.

Exciters for water wheel generators may be direct connected, belted, geared, or motor driven by an electric or water motor. The direct connected exciters are preferred because of their greater reliability.

Switchgear

Under the general heading of switchgear comes a variety of devices which may be considered the nerve center of the entire plant. This equipment performs extensive functions and is tailored to fit the operating methods adopted for the station.

The automatic hydroelectric unit by definition is one in which the generator is started and put on the line following an impulse received from a control device. The operating methods established for a particular hydroelectric generating plant will determine the origin of the starting impulse.

The starting impulse may be given by a local operator, by a remote operator through supervisory control equipment, or it may be given automatically by a float switch in the forebay, a time switch, or other device.

Regardless of the type of starting means employed, automatic units are protected continuously by devices which cause shutdown under abnormal conditions. After shutdown by protective devices, units which are started by a local operator or by supervisory control equipment usually must be given another starting impulse to restart the unit, regardless of the reason for shutdown Units which are started by a float switch, time switch, or other automatic device usually restart automatically after shutdown by protective devices when normal conditions again exist. When automatic restarting is employed, caution must be exercised in the design of the protective system, so that repeated unsuccessful attempts at restarting are not encountered.

There are two methods employed for accelerating and synchronizing a hydroelectric generator with a system. One method is known as self-synchronizing, and the other as automatic synchronizing.

In the self-synchronizing method, the generator circuit breaker is closed after the turbine has accelerated to approximately 95 per cent of synchronous speed. Field is applied after the generator circuit breaker is closed. For this type of synchronizing, the generator field is equipped with an amortisseur winding to develop synchronizing torque.

Self-synchronizing should be employed only on units which constitute a relatively small percentage of the total system capacity, as with this method a considerable amount of synchronizing power is exchanged with other units on the system. Self-synchronizing a large unit results in an appreciable voltage disturbance, therefore, it seldom is employed for units having more than 5,000 kw output

The automatic synchronizing method employs automatic speed matching and synchronizing equipment. This equipment connect the generator to the line at the proper speed, voltage, and phase angle.

The automatic synchronizing method makes it possible to connect a unit to a line with the least possible disturbance, regardless o the size of the unit. Automatic synchronizing is superior to manual synchronizing and often is employed in stations which do not have an automatic starting sequence.

After an automatic unit is in operation, the real and the reactive power delivered to the system may be controlled by a local operator, or by a remote operator through supervisory control equipment. Real power may be regulated automatically by load control devices or equipment responsive to headwater level.

The control equipment preferably is

Figure 3. Hydroelectric station showing generators, governor, and switchgear

Figure 4. Cutaway view of hydraulic turbine and connected generator

battery operated, as in general it is not desirable to depend upon the availability of a-c power for control functions.

Figure 5 shows the front and rear view of a typical tunnel type switchboard for an automatic hydroelectric station.

Automatic Sequences for Controlling Hydroelectric Stations

The following description treats independently the starting sequences for self-synchronizing and automatic synchronizing of hydroelectric generators. The schemes described are typical and would be altered in practice by changes in details to suit each particular application. The diagrams and description of operation apply to those automatic stations having a local operator, or those stations remotely operated through supervisory control. The diagrams and description apply to stations using reaction type turbines. The basic scheme involved can be modified to meet the operating requirements of the other three types.

Figure 6 shows a single line diagram which applies for either of the two methods of control; Figure 7 is a control diagram for the self-synchronizing method; and Figure 8 is a control diagram for the automatic synchronizing method.

Single Line Diagram

Figure 6 indicates the main connections of a hydroelectric generator, being of large enough size to warrant the use of a pilot exciter as well as a main exciter. Direct connected exciters are indicated.

A direct connected permanent magnet generator for operation of the governor flyball motor also is indicated. The governor flyball motor often is operated from potential transformers connected to the generator.

Instrumentation for local indications of electrical quantities is simple. Generator voltage, current, kilowatts, kilovars, and kilowatt-hours and bus voltage are the a-c quantities of interest. A synchroscope usually is supplied to provide a local indication of synchronism. Generator field current and main exciter field voltage are the d-c quantities which are of interest.

The telemetering transmitters, which would be desirable for a station operated by supervisory control equipment, are not shown on the diagram.

Self-Synchronizing Method

Starting

With reference to Figure 7, the *1 START* contact can be a contact on a local pushbutton or a contact operated by supervisory control equipment. If the lockout relays *86E* and *86N* are reset, the machine speed contact *14* closed, the generator circuit breaker *41* open, and, if the protective contacts connected across the coil of master relay *4* are open, master relay *4* will be energized. When master relay *4* picks up, it seals itself in around the momentarily closed *1 START* contact, as well as the *14* and *41* contacts. It will remain picked up unless short-circuited by the *1 STOP* contact, any one of the protective devices connected across the coil, or de-energized by either of the lockout relays *86E* or *86N*.

A make contact of relay *4* sets up a circuit to all the devices operated in the starting sequence. Relay *88QX* is operated immediately after *4* picks up to start operation of the bearing oil pumps. Incomplete sequence timing relay *48* likewise is energized immediately.

Adequate bearing oil pressure closes contacts *63QB*, and *63QX* is picked up. A contact of relay *63QX* energizes the governor solenoid *65S*, and the water wheel gates start to open under the control of the governor.

When the generator has reached 95 per cent of synchronous speed, contact *13Y* closes, which completes a circuit to the closing relay of the generator circuit breaker *52*. Closing of the generator circuit breaker completes a circuit to the closing relay of the generator field circuit breaker *41*. Thus, the generator is connected to the system at slightly less than synchronous speed, and its field is applied immediately thereafter. The field circuit breaker de-energizes the incomplete sequence relay.

After the generator is connected to the system, the load can be adjusted by means of the governor synchronizing motor, or it can be arranged to take a

Figure 5. Front (left) and rear view (right) of a typical tunnel type switchboard for a hydroelectric station

load automatically, depending on the governor load limit setting.

STOPPING

The *1 STOP* contact can be a contact on a local pushbutton or a contact operated by supervisory control equipment. When the *1 STOP* contact is closed momentarily, it short-circuits relay *4* and causes its release.

When relay *4* releases, it de-energizes the governor solenoid *65S* and the bearing oil pumping motor relay *88QX*. A time delay circuit not shown continues the oil pump motor operation for a definite period of time after the release of relay *88QX*. Release of the governor solenoid causes the turbine gates to start to close. When the gates reach the no-load position, gate contact *33NL* closes. Closing of this contact completes a circuit which sequentially trips the generator circuit breaker and the field breaker. Thus the generator is disconnected from the system with no disturbance, as the load had been dropped gradually before the generator circuit breaker was opened.

The turbine gates continue to move until they reach the fully closed position. When the gates are closed completely, gate interlock *33Z* operates brake relay *20*, providing contacts *14*, *4*, and *52* are closed. Through circuits not shown, relay *20* causes the turbine brakes to be applied for a definite period of time, assuring that the machine is brought to a stop.

Automatic Synchronizing Method

STARTING

It will be noted from Figure 8 that the circuit for energizing relay *4* is the same as shown in Figure 7, except that it is unnecessary to check the position of the field circuit breaker *41* before starting. When relay *4* picks up, it seals itself in around the momentarily closed *1 START* contact as well as the contact of device *14*. Just as in Figure 7, it will remain picked up, unless short-circuited by the *1 STOP* contact, any one of the protective devices connected across the coil, or de-energized by either of the lockout relays *86E* or *86N*.

The operation up to the energizing of relay *63QX* is the same for automatic synchronizing as for self-synchronizing.

When relay *63QX* picks up, the governor solenoid *65S* is energized, automatic synchronizing and speed matching auxiliary relay *25X* is energized and the generator field circuit breaker *41* is closed. Thus, the water wheel gates start to open under the control of the governor, the generator field current builds up as the exciter comes up to speed, and the speed matching and automatic synchronizing equipment is energized.

As the generator comes up to speed, the speed matching equipment functions to match the generator frequency with the line frequency, and the voltage regulator adjusts the field current for line voltage.

When the instantaneous frequency difference and the phase angle difference are satisfactory for proper synchronizing with the system, automatic synchronizing contact *25* is closed to energize the generator circuit breaker closing circuit. Closing of the generator circuit breaker de-energizes relay *25X* and takes the automatic synchronizing and speed matching equipment out of service.

The incomplete sequence relay is de-energized when the generator reaches 95 per cent speed. The synchronizing time is variable and hence is not included in the over-all timing of device *48*.

Where it is required that the generator energize a dead bus, the contact of relay *25* in the foregoing description must be paralleled by a contact of a dead bus relay in series with a synchronous speed contact.

STOPPING

The normal shutdown by operation of the *1 STOP* contact is exactly the same as was described previously for the self-synchronizing system.

Hydraulic Governor

The over-all arrangement of the mechanical parts of a typical hydroelectric station is shown in Figure 9. On the shaft of the water wheel generator, a permanent magnet generator is shown. Three-phase power from this generator drives a flyball motor at a speed synchronous with that of the generator shaft. The flyballs deliver an indication to the governor in proportion to their speed of rotation. This indication is applied to the power cylinder and amplified by hydraulic means. Compensating devices provide the antihunting characteristics of the governor. Within the mechanism there are facilities for changing speed, limiting gate opening, and controlling the speed droop characteristic of the governor.

The pilot valve of the servomotor is controlled by the motion of the rod connected to the flyballs. This pilot valve controls the relay valve which in turn controls the power cylinder that operates the gates.

The mechanical feedbacks from the relay valve and power cylinder are used to operate the mechanism which obtains a motion of the power cylinder proportional to the motion of the speeder rod and at the same time allows the speeder rod to respond to the resulting change in speed without further change in gate position.

The power for the operation of the relay valve and power cylinder is obtained from an oil pump which stores oil in a tank against a head of air.

Details of governor operation are of

Figure 6. Single line diagram of a single unit hydroelectric generating station

interest because the automatic control functions with it. Figure 10 is an arrangement of devices analogous to an actual governor. In practice the linkages and compensator take a form more convenient and practical.

Assume, in Figure 10, that the speeder rod is in a given position, the floating lever is level, the pilot valve is on neutral, the relay valve is on neutral, and the power cylinder is in a given position.

Now assume that the flyballs depress the speeder rod in response to an increase in speed. The left end of the floating lever is depressed, pivoting about point *A*. The pilot valve is pushed to the close position by rod *1*. The relay valve, under force of hydraulic pressure received from the pilot valve, travels to the close position and through bell crank *1* lifts the pilot valve to the neutral position by pivoting lever *1* around point *C*. The relay valve stays at the closed position admitting oil under pressure to the power cylinder, driving the gate rod in closing direction. In response to this motion, bell crank *2* drives the pistons of the compensator upward in unison against spring pressure. This causes the floating lever to pivot about point *D* raising rod *1* and the pilot valve to the open position. The relay valve in response to this action, moves towards the open position but halts at neutral when its motion, transmitted through bell crank *1* lowers the pilot valve to neutral. The governor thus has moved the gate rod a definite distance in response to a definite motion of the speeder rod.

The next sequence of events prevents a change in gate rod position, as the speeder rod changes position in response to the asked for decrease in speed. Following the action described in the last paragraph, the floating lever is subject to a spring pressure tending to lower its right end and a change in flyball pressure, due to decreasing speed, that tends to raise the left end. An adjustment of the needle valve in the compensator can be made, so that the right end of the lever will lower at a rate matching the rising of the left end as the floating lever revolves about point *B*. When this condition exists, rod *1* will not move, and therefore, no gate motion can result from the speeder rod movement.

In Figure 11 further details of the governor are shown. Speed or load adjustment is accomplished by changing the speeder spring pressure. This is done remotely from the governor by energizing the synchronizing motor. This motor drives a lead screw upon which is mounted a traveling nut. The base of the speeder spring is raised by the traveling nut to increase its pressure and lowered to decrease it. Limit switches sometimes are provided to limit the range of speed adjustment.

Speeder spring pressure also is raised and lowered by the action of the speed droop mechanism. As the power cylinder moves in a direction to open the gates, the speed droop mechanism decreases spring tension, thereby satisfying the governor balance at a lower speed than would be the case if there were no speed droop device.

It will be noted from this arrangement that the height of the orbit of the flyballs and the corresponding position of the speeder rod depends upon the speed of the flyballs and the speeder spring pressure. As the spring pressure is increased, the turbine will be required to take more load at a given speed. Likewise, at a given load, such as would be experienced during starting, increased spring pressure develops increased speed.

Since the operating speed varies only slightly during normal operation, the position of the speeder rod will be an index of the load being carried. Consequently, a load limit device can be made to operate on the speeder rod merely by limiting its excursion toward the open position.

The automatic starting and stopping control works on the mechanism of the load limit device.

To put the turbine in operation, the starting solenoid must release the gate lock and open the gates quickly to the point at which the wheel starts turning.

If a permanent magnet generator is employed to drive the governor flyball motor, the governor takes a control as soon as the generator starts to rotate. However, if the governor flyball motor is energized from potential transformers connected to the generator, the gate open-

Figure 7. Typical schematic diagram for self-synchronizing starting method

Figure 8. Typical schematic diagram for automatic synchronizing starting method

ing is under control of a timer until excitation appears and makes voltage available to the governor flyball motor.

With reference to Figure 11, operation of the starting solenoid actuates a valve which causes the pilot and relay valves to be energized and the gate lock released. Another valve releases the pressure in the control cylinder, and the spring attached to the control level causes it to descend rapidly until it engages the timer. The descent is slower after the timer is engaged and thereby limits turbine acceleration until the exciter voltage builds up.

To shut down the turbine it is required that the gates be closed slowly to the no-load position before the circuit breaker opens. De-energization of the solenoid opens a valve which allows the control lever to raise slowly and close the gates. The oil to the gate lock cylinder, pilot valve and relay valve is shut off slowly. Spring pressure firmly applies the gate lock and maintains it a long as the machine is shut d.wn.

Contacts are connected to the gate rod and are used with the automatic control to indicate zero gate opening and full-speed no-load gate opening. Contacts for operating the automatic control functioning in response to speed changes are provided on either the generator shaft or the permanent magnet generator shaft.

Voltage Regulator

A voltage regulator applied to a hydroelectric generator provides a method of maintaining a desired voltage at that point and of adjusting for the amount of reactive power which it is desired to have the generator furnish. The latter adjustment is made possible by the fact that a change in the field current of a generator connected to a system does not change its load but does change its power factor. A decrease in the generator field current makes its power factor less lagging, and an increase in its field current makes its power factor more lagging. Thus, to vary the reactive load taken by the generator, it is merely necessary to change the adjustment of the voltage regulator

A typical voltage regulator, suitable for either automatic or self-synchronizing is shown in Figure 12. It is brought into service by the closing of generator circuit breaker *52*, providing the transfer switch is in the regulating position. The regulator transfer switch has "Manual", "Indicating," and "Regulating" positions. In the "Manual" position, the motor-operated rheostat may be raised or lowered by hand through the contacts *CSR* and *CSL* of a local control switch. In the "Indicating" position, the voltage regulator performs all its functions, except that it does not move the motor-operated rheostat. In the "Regulating" position, the voltage regulator is in full operation.

The d-c motor which drives the motor-operated rheostat has a split series field. Energization of the armature in series with one field will raise excitation, the other will lower excitation. Limit switches prevent excessive travel of the mechanism. Cam switches are connected in the rheostat motor circuit to run the rheostat to the no-load position after the generator field circuit breaker *41* opens on shutdown. It is sometimes preferred to have the regulator in service before the generator is connected to the line. For such operation, the cams can be eliminated on the exciter field rheostat, and the voltage adjusting rheostat can be equipped with cams to return the motor-operated voltage-adjusting rheostat to the no-load position when the machine is shut down. For either arrangement, no-load field excitation is present during starting of the generator.

Contactors *NR* and *NL* control the exciter rheostat motor under direction of the voltage element of the regulator. The latter is connected to generator potential transformers as shown in Figure 12.

An indication comes from the voltage regulator element that a raise in excitation is necessary by the closing of contact *VR*. Contactor *NR* is picked up by this action, and it operates the motor-operated rheostat and antihunt coil *NH*. The latter functions to open contact *VR* mechanically before a rise in voltage is effected by the generator. Contact *VR* closes again, if, after a time delay, an adequate rise in voltage is not effected. Similarly, a demand for reduction in voltage involves contact *VL*, contactor *NL* and antihunt coil *NH*.

Sudden wide changes in voltage demand more rapid changes in excitation than normal operation through the motor-operated rheostat will provide. In this

Figure 9. General schematic of water wheel governor

case, contacts *AR* and *AL* operate the quick raise contactor *QR* or the quick lower contactor *QL*. These contactors energize the antihunt coil *QH* and also switch the field forcing or field reducing resistors into the circuit.

With generators operated in parallel, the division of kilowatt load between the machines is unaffected by the voltage regulator, but the division of reactive power is affected directly by the operation of the regulator. In cases where the reactive drop between generators is low, such as in feeding a bus directly and not through transformers, satisfactory operation may be obtained by giving the regulator a drooping characteristic from a cross current compensator energized from a current transformer.

The motor-operated voltage-adjusting rheostat shown in the circuit of the voltage element of the regulator in Figure 12 provides a means of setting the regulator to regulate the voltage at the value at which it is to be maintained. If there is an operator at the station, the voltage-adjusting rheostat need not be motor operated. If the station is to be remotely controlled, the voltage adjusting rheostat will be motor operated when the reactive power flow is to be adjusted remotely and manually operated when a fixed setting is adequate.

Automatic Synchronizer and Speed Matcher

Figure 13 shows the connections of a speed matcher and an automatic synchronizer. It will be noted from this diagram that the speed matcher and automatic synchronizer are put into service when relay *25X* is energized.

The balanced torque type speed matcher indicated is a device in which two synchronous motor-driven centrifugal devices develop opposing torques on a balanced beam. When the torques are unbalanced, the beam will close one or the other of two contacts, depending upon which torque is the greater. These contacts are connected to auxiliary relays *15BX* and *15GX*. Contacts of relays *15 BX* and *15GX* operate in the circuit of the governor synchronizing motor to raise or lower the speed of the generator. Thus, the speed matcher properly adjusts the speed of the generator, so that the automatic synchronizer can close the generator circuit breaker.

An automatic synchronizer should meet the following requirements:

1. The circuit breaker closing coil should be energized at an exact time in advance of synchronism, so that the time consumed by the circuit breaker in closing is just equal to the time consumed by the generator in arriving at exact synchronism.

2. The synchronizer should close the circuit breaker only if the frequency difference between the two voltages is less than a predetermined value.

These requirements are met by the automatic synchronizer shown in Figure 13. The synchronizer is connected to the generator and bus potential transformers to give a dark lamp beat voltage across dry-type full-wave rectifiers *1* and *2*. The

Figure 12. Typical voltage regulator schematic

dry type rectifier output voltage is essentially a pulsating direct voltage of sine wave form, having a frequency equal to the frequency difference between the generator and bus voltages.

A constant negative bias is applied to triode *1* through adjustable resistor *X* and a constant negative bias is applied to triode *2* through adjustable resistor *Y*.

The output of rectifier *2* provides a negative bias for both the triodes which is proportional to the phase angle difference between the generator and bus voltages. Thus, minimum negative bias is obtained when the phase angle difference is zero. This being the only varying bias on triode *2*, adjustment of resistor *Y* makes it possible to have relay *25C* energized at any desired phase angle difference between the two voltages.

Triode *1* is furnished with a second varying bias from the output of rectifier *1*. When the frequency difference is zero, the voltage across capacitor *C* is equal to the output voltage of rectifier *1*. When the phase angle between the generator and the bus voltages is changing from 180 degrees towards zero, the output voltage of rectifier *1* decreases, leaving the voltage of capacitor *C* higher than the output voltage of the rectifier. The amount the capacitor voltage is higher than the rectifier voltage under this condition is proportional to the frequency difference. The discharge current of the capacitor *C* produces a voltage drop across resistor *Z*, the magnitude of this voltage being proportional to the frequency difference. The voltage across resistor *Z* provides a varying bias to triode 1 in addition to the varying bias provided by the output of rectifier *2*. Thus, triode *1* is provided with a bias that varies with the actual phase angle difference, as well as the rate at which the phase angle is changing. Resistor *X* is adjusted so that the constant negative bias provided is just low enough to operate relay *25B* at zero phase angle difference when the frequency difference is zero. Relay *25B* then will operate at an advanced phase angle position, the amount of advance being proportional to the frequency difference. The amount of phase angle advance desired is obtained by adjustment of resistor *T*.

Figure 15 indicates the operating characteristics of relays *25B* and *25C*. Relay *25B* closes its contacts at a phase angle in advance of synchronism proportional to the frequency difference between the two voltages according to line *a*. Relay *25C* closes its contacts at a fixed phase angle in advance of synchronism according to line *b*. The intersection of lines *a* and *b* of Figure 14 indicates the maximum frequency difference between the two voltages at which the circuit breaker will be closed.

Figure 13. Automatic synchronizer schematic

Figure 14. Operating characteristics of relays in the automatic synchronizer

Relays *25B* and *25C* are interlocked so that relay *25C* must operate before relay *25B*. This interlocking makes the synchronizer meet the requirements for proper synchronizing previously listed.

Relay *25A* interposes a time delay corresponding to one period of the slip frequency when the automatic synchronizer is placed into operation to prevent the synchronizer from functioning until the voltages on the component parts are stabilized.

Relay *25* is energized by relays *25B* and *25C* to energize the generator circuit breaker closing circuit. This relay can not be energized if either of the triodes fail.

Protection

The American Standards Association lists the following minimum protection for automatic hydroelectric generators.

1. Alternating overvoltage.
2. Single phase operation.
3. Thermal overload.
4. Overspeed.
5. Loss of field (lockout).
6. Differential protection (lockout).
7. Bearing overtemperature (lockout).

The protection provided for automatic stations in addition to that listed is dependent on the size of the machine, the location, and other factors. Also, exactly what is done on the operation of various protective devices is dependent on the particular installation. For stations with an operator, or those controlled by supervisory control equipment, the functioning of the various protective devices can be grouped under four different headings. The following listings under these headings are typical and would not necessarily function as indicated on all installations.

Immediate Shutdown and Lockout

1. Generator field failure.
2. Generator differential relay operation.
3. Transformer differential relay operation.
4. Generator overvoltage.
5. Low station battery voltage.

Normal Shutdown and Lockout

1. Generator bearing overtemperature.
2. Turbine bearing overtemperature.
3. Phase unbalance.
4. Generator ground relay operation.

Normal Shutdown Without Lockout

1. Overspeed.
2. Generator thermal overload.
3. Governor oil pressure failure.
4. Single or reverse phase.
5. Generator overcurrent.
6. Transformer overtemperature.
7. Generator winding overtemperature.
8. Incomplete starting sequence. (Often used to lockout).
9. Bearing oil pressure failure. (Often used to lockout).

Annunciator and Alarm—No Shutdown

1. Loss of generator bearing cooling water.
2. Loss of turbine bearing cooling water.
3. Low generator bearing oil level.
4. Low turbine bearing oil level.
5. Low transformer oil level.
6. Low governor oil level.
7. Loss of cooling air flow.

Figure 15 shows a typical lockout and annunciator circuit arrangement for the protective features just listed. Lockout relay *86E* is energized by operation of the devices listed for immediate shutdown and lockout. Bus differential would be included in this group in those stations where it is employed. It will be noted from Figures 7 and 8 that operation of lockout relay *86E* immediately trips the generator circuit breaker *52* and the generator field circuit breaker *41* and also de-energizes master relay *4*. On operation of the protective devices which operate lockout relay *86E*, it is desirable to disconnect the generator from the system as soon as possible without waiting for the turbine gates to reach the no-load position.

Lockout relay *86N* is energized by operation of the devices listed for normal shutdown and lockout. As shown in Figures 7 and 8, operation of relay *86N* only opens the circuit to the master relay *4*. The shutdown for this operation is the same as a shutdown by operation of the *1 STOP* contact as previously described.

Lockout relays *86E* and *86N* both must be reset manually before the generator can be restarted.

The protective devices for normal shutdown without lockout operate directly on master relay *4*. Figures 7 and 8 show each of these protective devices short-circuiting the coil of relay *4* to cause it to release and open its seal-in contact. Shutdown thus follows the same procedure as for shutdown by operation of the *1 STOP* contact. When shutdown results from any of these conditions, the unit can be restarted without the necessity of manually resetting any devices.

The last group of protective devices listed only operate annunciator drops and

Figure 15. Typical lockout and annunciator schematic diagram

Figure 16. Schematic diagram for motor operated controls

sound an alarm as shown in Figure 15. All of the other protective devices which shutdown the unit also are shown operating annunciator drops and sounding the alarm.

The annunciator consists of drops and a latching type alarm relay *30*. Operation of any of the protective devices energizes an individual drop in series with the operating coil *30O* of the latching relay. Operation of the annunciator drop opens its circuit. Operation of relay *30* completes a circuit to the alarm bell.

Closing the bell cutoff contact energizes the reset coil *30R* of the latching relay and silences the alarm.

Governor and Regulator Control

Figure 16 shows split series field motors for the four controls which make it possible to adjust for the desired operating characteristics. The *Raise–Lower* contacts indicated can be contacts of local control switches or contacts actuated by supervisory control equipment. It is to be noted that the governor synchronizing motor also is controlled by contacts of the speed matcher when automatic synchronizing is employed.

Supervisory Control

Remote control equipment often is applied to automatic hydroelectric stations. Economic considerations usually dictate the use of supervisory control equipment to provide the necessary controls and indications.

Supervisory control equipment as manufactured today can be operated over a single pair of telephone wires, a power-line carrier channel, or a space radio channel. The single channel means is all that is required for the necessary controls, amp indications, and selective telemetering indications. This is indicated in block diagram form in Figure 17.

1. *Start-Stop* control of generators with supervision of generator circuit breakers.
2. Control of governor synchronizing motors with simultaneous telemetering of real power output.
3. Control of regulator voltage adjusting rheostats with simultaneous telemetering of reactive power output.
4. Control and supervision of other circuit breakers in station.
5. Supervision of generator lockout.
6. Supervision of annunciator.
7. Supervision of *Local-Remote* transfer switch.
8. Telemetering of bus voltage.
9. Telemetering of headwater level.
10. Communication.

Other functions which may be performed by the supervisory control are dependent on the requirements of the particular installation. The following additional functions sometimes are provided by the supervisory control equipment.

1. Control of governor gate limit with simultaneous telemetering of gate limit position.
2. Control of governor speed droop with telemetering of speed droop position.
3. Control and supervision of headwater gates or valves.
4. Control of diversion and reject spill gate position with simultaneous telemetering of gate position.
5. Supervision of door giving access to hydroelectric station.
